

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

INDEX TO VOL. I. (New Series.)

Actinometer, Electric, 532.
Accumulators, *see* BATTERIES, SECONDARY.
Adelaide Exhibition, 265.
Admiralty, Report of Engine Room Telegraph Committee, 482.
Aerial Conductors and Loss of Electricity, 121.
Alarm Clock, Electric, 433.
Alcohols, Electric Disinfection of, 230.
Alkalies and the E.M.F. of Zinc, 269.
Alloys, Electrolytic Preparation of, 51.
Alternate and Continuous Systems, 234, 305, 524.
Alternating Currents, Tesla's System, 493, 568, 583, 601, 609.
Aluminium, Cowle's Process for Obtaining, 145, 577.
Aluminium, Electro-deposition of, 73, 145.
America, Prospects in, 467.
America, Telegraphy in, 97.
American Institute of Electrical Engineers, 26, 483.
American National Electric Light Association, 241, 301. (*For papers read at, see names of authors and subjects.*)
Amiens Industrial Society, Prize offered by, for Factory Lighting, 73.
Ammeter, Sesemann's, 195.
Ampere Meters, *see also* METERS.
Ampere Standard, Pollat's, 51.
Andrews, J. D. F., Earth Systems for Electric Lighting, 438, 457, 482.
Anglo-American Brush Co.'s Meetings, &c., 214, 238.
Anglo-American Brush Co.'s Works, 147.
Anglo-American and French Cable Co.'s Dispute, 408.
Anglo-American Telegraph Co., Meetings, &c., 96, 120, 133, 142, 383, 388.
Anthony, W. A., Electrical Measurements, 92, 115, 141.
Antimony Ores, Electrolytic Treatment of, 101.
Antwerp Exhibition, Report on Arc Lights, 252.
Appointments, 49, 434, 457, 555, 578.
Arc Installation for Railways, Travelling, 370.
Arc Lamp, Cance's, 410.
Arc Lamp, Zone of Maximum Intensity, 259.
Arc Lamps, Hardtmuth's Carbons for, 315, 386.
Arc Light Wires, Undergrounding of, W. W. Leggett, 304, 332.
Arc Regulator, Perthier's Hydraulic, 88.
Arc Regulator, Pollak's, 436.
Armstrong's Electric Light Company, 240.
Arthur-street East Extension, 339.
Artistic Fittings for Electric Lamps, 486.
Arts Society—Meetings, Lectures, &c.—*Conversations*, 579.
Crompton, Central Station Lighting, 474.
Lodge, Protection from Lightning, 243, 277, 613.
Preece, W. H., Application of Electricity to Lighting, 88, 164, 178.
Atlantic Cables—Impending Compromise, 101, 133, 148, 158.
Atlantic Cables, More, 98, 145.
Atlantic Cables—Pouyer-Quertier v. Anglo-American Company, 27.
Atlantic Cables, The Tariff War, 158.
Atmospheric Electricity, 125, 284.
Aurora Borealis, Origin of, 564.
Australia, Telegraphic Communication in, 340.
Australia and Vancouver, Proposed Cable between, 241.
Austria, Telephone Company of, 336, 620.
Auzanoscope, Trouvé's, 361.
Ayrton and Perry, Efficiency of Incandescent Lamps, 512.
Ayrton and Perry, Governing Motors, 548.
Ayrton and Perry, Measuring the Coefficient of Heat Expansion, 474.
Ayrton and Perry, Voltmeters, 20, 43, 67.
Ayrton, Mrs., Syllabus of Lectures by, 27.

B.

Babcock, P. G. H., Electricity and the Mechanical Engineer, 65.
Badi, F. B., Continuous v. Alternate Systems of Lighting, 524.
Balance, Composite, Sir W. Thomson, 464.
Balance, Maquaire's, Electro-Dynamic, 107.
Balance, Electric, see also METERS.

Balearic Islands, New Cable to, 289.
Balloons for the Italian Army, 27.
Bandsept, A., appointed Chief Engineer, Brussels Exhibition, 49.
Bandsept, A., Electrical Traction, 375.
Barcelona Exhibition, 171, 242, 267, 313, 457, 602.
Barometer, Electrical, 266.
Barton, S. E., Electric Lighting and Fire Insurance, 494.
BATTERIES, PRIMARY—
Bradley's, 97.
Carbon as a Positive Element in, 3.
Clark's Standard Cell, D. G. Fitzgerald, 16.
Cox's Portable Cell, 49.
Effect of Chlorine on E.M.F., G. Gore, 470.
for Electric Lighting (a good word), 169.
E.M.F. of Various, 603.
Gassner's, 608.
Ménard's Soap, 385.
Possibilities of, F. B. Crocker, 544.
Rénard's, 506.
Schanschiff's, 219, 325, 505, 554.
Weymersch's, 593.
Wright's Experiments with, 74.
BATTERIES, SECONDARY—
on board ship, 553.
Carbon Electrodes, 581.
Carrière's, 194.
Cely's, 169.
Commelin's, 339, 556, 566.
Drake and Gorham's Excess Indicator, 182.
For Electric Lighting, 77, 145, 198, 254, 274, 289, 342, 348, 378, 403, 428, 451, 500, 505, 553, 556, 577.
For Electrical Traction, 1, 124, 146, 194, 315, 375, 435, 457, 537, 540.
Epstein's, 529.
The E.M.F. of, 169, 338, 556.
Evidence of Efficiency of, 434.
Experiments on, at Vienna, 170, 194, 507.
Haupt Company v. Philippart, 237.
Messrs Philippart's Action in France, 338, 361.
Formation of Hydrogen Peroxide, 340.
Gilson's Plates for, 433.
Julien's, 1, 146, 194.
Management of, Sir D. L. Salomons, 346.
Prof. Martin's Report on, 410.
New Types of, 556.
New Work on, by M. Reynier, 409.
Patonson and Cooper's Cut-Out, 350.
Porous Electrodes, 339.
Instead of Primaries for Exchange Company's Work, 49.
Silica, in, 601.
Some Points in, D. G. Fitzgerald, 33.
Sprague's, 268.
Or Transformers, 198, 254, 274, 342, 348, 378, 403, 428, 451, 500, 543.
Tudor's, 50, 556.
A Waste Product (*cum grano salis*), 123.
Bearings, Hot, Detection of, 580, 611.
Beaumont's Variable Speed Mechanism, 607.
Belgian Academy of Sciences, Prizes offered by, 530.
Belgian Society of Electricians, Prize offered by, 435.
Bell Company's Output, 50.
Bell Company v. Aloe and Others, 74.
Bell, Prof. Graham, Visit to England, 529.
Bell Telephone Case, 218, 326, 386.
Bentley-Knight Electric Railway, 182, 217, 225.
Berlin Telegraph Office, Busy Day at, 243.
Berliner's Gramophone, 25.
Berly's Electrical Directory, 185.
Bessierok and Newry Tramway, Dr. Hopkinson, 265, 349, 353, 376, 400, 423.
Bicycles, Electric Welding for, 458.
Biographies, with Portraits—
Davy, Sir H., 371.
Graves, E., 13.
Wellaston, Dr., 109.
Birch, An Electric, 75.
Bismuth, Heat Conductivity of, 217.
Blackburn Technical School, 457.
Blackwell, R. W., Electric Tramways, 279.
Blakesley, T. H., Magnetic Lag in Transformers, 473.
Bleaching, Electrolytic, 442.
Boats, Electric, 148, 506.
Boats, Trouvé's Motors for, 435.
Body, Protection from Dangerous Currents, 573.
Boiler Inspection, Incandescent Lamps for, 554.

Boilers, High-pressure, 530.
Boilers, Water-Level Indicators for, 362.
Books received, 25, 164, 169, 181, 217, 231, 385, 433, 529, 577, 602.
Books, Reviews of, *see* LITERATURE.
Boot-Blackening Machine, Electric, 505.
Bottomley and Thompson, Reduction of Chl rates, 3.
Brazilian Submarine Telegraph Company, 43.
Bright, Sir O. T., Obituary Notice of, 439, 440.
Brighton Electric Light Company, 166, 193.
Brighton Electric Railway, 564.
Brighton Railway and Carriage Lighting, 140.
Bristol, University College, *Conversations*, 313.
Britannia Company's Lathes, 497.
British Association at Bath, 25, 409, 484.
British Association of Medical Electricians, 578, 601.
Brook's-Pell Arc Lamp for Lecture Lantern, 57.
Brush Transformer System, 558, 577.
Brussels Electric Tramway, 146, 267, 315, 378.
Brussels Exhibition, 85, 94, 147, 173, 202, 457.
Bullet Probe, Electrical, 460.
Buoys, Electric Lighting of, 1.
Bucy, A Self-Luminous, 99.
Burchell, —, Death of, 531.
Burglar Alarm, The True, 457.
Burnish, Telegraphs Interrupted in, 409.
Business, In the Way of, 85.
Business Methods, 7.

THE ELECTRICAL ENGINEER

No. 1. Vol. 1.—New Series.

LONDON, JAN, 6, 1888.

Price 3d.

NOTES.

Leiz. The electric light at this castle has proved so successful that the Emperor has decided to have the lighting extended to every room.

Lighting Trains in Russia. The carriages and engines of the express trains on several of the Russian trunk lines are now lighted by electricity.

Stalybridge. Mr. R. Platt's mills in Quarry-street are lighted by electricity, and the workpeople are unanimous in preferring the healthy light of electricity to that of gas.

Vienna. Better accounts of the lighting of the opera are being received, and it is stated an extension of the lighting at the Town Hall has been decided upon by the municipal authorities.

The Jullien Accumulator. In this apparatus, the plates supporting the active materials are formed of an alloy of lead, 3.5 antimony, and 1.5 mercury, which is stated to be inoxidisable.

Shop Lighting. Messrs Chas. Baker and Co., of Fleet-street, have just lighted their premises by the electric light. For this purpose the Jablochkoff lamps are used, the current is supplied from Holborn.

Electrical Traction.—According the *Bulletin Technique de la Société des Anciens Elèves des Ecoles Nationales Supérieures d'Art et d'Architecture*, the first experimental trials in the use of accumulators in electrical traction were made at Paris in 1882.

The Use of Telephones in America. The manager of a New York telephone company states that on a recent day they received an average of 7½ calls from each of their over 7,000 subscribers. One subscriber made 68 calls and another received 131 calls.

City and Guilds Institute.—It is stated that the Hon. secretaries (Mr. W. P. Sawyer and Mr. John Watney) will not again offer themselves for reelection. The services of these gentlemen have extended over a period of upwards of ten years.

Experiments in Lighting Buoys.—The United States Lighthouse Department have had a series of experiments carried out by Lieutenant Willis to ascertain the

value of lighting spar buoys by incandescent lamps, the current required being carried by cables from the shore.

Berlin.—This city will soon be the most brilliantly-illuminated city in Europe. The electric light is being fitted all along the Unter den Linden, and the Leipziger Strasse, which is upwards of a mile in length, is already illuminated throughout by electricity, which is to be introduced into all the principal streets and squares.

Londonderry. The question of lighting the city by electricity is under discussion, and the solicitor has been instructed to put before council the existing agreements between the gas company and the corporation, and to obtain legal opinion as to the powers of 'the corporation' to enter into the proposed scheme.

Sweden.—The town of Falu in Sweden is about to be lighted by electricity, a mode of illumination already adopted in two or three other Swedish towns. The installation is intended to comprise 50 arc lamps of 1,200 candle power each, and 300 incandescent lamps. The available power admits of a further increase of 200 incandescent.

Manchester "Wild West" Show. Messrs. Hornsby and Sons have obtained the contract for the whole of the engine and boiler power for the electric lighting, heating, and ventilating of the large building which is being erected in Manchester for the purpose of the "Wild West" Show.

"Sithee for Thisen."—A man reading not a mile from Ringinglowe, whose younger brother had been working at the gas-house for about a fortnight, was one night walking through the town, and seeing the electric light for the first time, exclaimed to his pal, "By gum, aw! tell thee what, lad—ah! mypers made a bit o' difference tu t' gas be nahr. Sithee for thisen." Jokes of the *Sheffield Telegraph*.

Electric Lamps for Submarine Work. Experiments made at Newport with incandescent electric lamps show that if a 100 candle lamp is submerged below the surface of the sea the water is illuminated so that objects are visible in it at a distance of 150ft. It is expected that this device will be useful in warfare for determining the positions of, and destroying the cables of an enemy's mines.

Bournemouth.—The question of lighting the pier and pleasure grounds by means of the electric light is not to be allowed to drop. The experiments conducted by Messrs.

Mortimer, Shepherd and Co., during the past summer season were a great success, and it is hoped the Commissioners may soon see their way to permanently light the pier and the pleasure gardens.

Folkestone. It is said that Folkestone is about to adopt the electric light, and that Messrs. Laing, Wharton, and Down, electrical engineers, Holborn Viaduct, E.C., will shortly put down appliances for 10 lamps of 1,200 candle power. These lamps will be run for a month on trial. It is also stated that a company is being formed for the purpose of supplying the electric light to Tunbridge Wells.

The Great Eastern.—The Great Eastern has been purchased by a Liverpool firm of metal merchants, whose intention is to break her up in the course of the next few months, and sell her as old metal. This magnificent vessel, whose gross registered tonnage is 18,915 tons, length 692ft., breadth 83ft., and depth 60ft., has been sold at the price of £16,100, or very little more than one-fourth of the sum it cost to launch her.

Institute of Electrical Engineers.—We hardly know when this new name is to take effect, but meanwhile the meetings announced for this year to be held by the permission of the Institution of Civil Engineers at 25, Great George-street, Westminster—are fixed for the following Thursday evenings: January, 12 and 26; February, 9 and 23; March, 8 and 22; April, 12 and 26; May, 10 and 31; November, 8 and 22; and December 13. On Thursday, January 12, the President (Edward Graves, Esq.) will deliver his inaugural address. The meeting on December 13 is the annual general meeting.

Glasgow Technical College. A steam engine, which might be termed an educational engine, has been presented to this institution by Mrs. Russell in memory of her husband. The engine has been specially designed by Prof. Jamieson, of the college, as an educational machine to enable engineering students to make accurate tests not only of the weight of steam and (or) condensing water required under different circumstances, but also to drive the college dynamos for charging storage cells and working electric arc or incandescent lamps. The engine will develop about five indicated horse power with the present available steam supply, which is obtained from Mr. Gray's works adjoining the college; but all the working parts have been calculated for a steam pressure of 100lbs. per square inch, and 200 revolutions of the crank shaft per minute.

Heat of Frictional Electricity. It has recently been shown M. Semmola that a metallic point through which negative electricity is discharged, giving in the dark the appearance of a star, is heated to a greater extent than a similar point traversed by a brush discharge of positive electricity. The metallic point used in his experiments was formed of strips of antimony and bismuth soldered at their extremities, and thus forming a thermo-electric couple. The elements of this couple being respectively connected with the terminals of a galvanometer, this was deflected when a discharge traversed the point. The discharge-point of M. Semmola might possibly be utilised in indicating the electrical disturbances which precede thunderstorms; in this case the metals composing it may advantageously be iron and platinum.

Phoenix Fire Office Rules. The 11th edition of these rules has just been issued, and it will be necessary for all those concerned in drawing out specifications, or in carrying out installations, to make themselves thoroughly conversant with the additions that are to be found in this edition. They are principally in regard to transformers, and are to be found in paragraphs 19 and 20 on pages 9, 10, and 11. We are glad to see an effort made in printing these rules to assist the reader to easily refer to the subject matter of the paragraph. We would suggest with the next edition that an index be added, when the pamphlet will almost come up to the ideal one according to American notions. As is well known, Mr. Musgrave Heaphy, who is responsible for these rules, is always willing to receive and consider any suggestions which may be put forward by practical men for their improvement.

Underground Wires. The *New York Sun* says: "A new device for protecting the cables of the electrical subway has been invented by Gen. W. W. Averell, U.S.A., and will be tried on Spring and Green streets. Spring street has already been opened from Broadway to Green for the purpose. A boxing of hardened wood has been laid in the trench, and eighteen 2½ in. iron tubes will be conveyed through it to carry the cables. The box will then be filled in with Trinidad asphalt melted up with sand. The mixture will be poured in hot, and worked in between the pipes, entirely separating them and making a solid stone-like mass. Gen. Averell thinks it will withstand age, moisture and corrosion better than any of the preparations tried in different parts of the city. Most of the work throughout the city is similar in method to this new device, but substitutes cement for asphaltic concrete."

Telephones instead of Speaking Tubes. The Equitable Telephone Association (Limited) have in hand installations of their Swinton Telephones, to be used as a substitute for speaking tubes in large buildings. Among these is an installation of 27 telephones in the new offices and ware rooms of the Co-operative Wholesale Society, and another is in the Hospital for Consumption at Ventnor. In the latter case all the various wards, the porter's lodge, and the house of the resident doctor will be connected together. The same company have quite recently completed a similar installation in the offices and warehouse of Messrs. Lyons and Co., 27, London-wall, the various floors of the warehouse, and the clerk's and private offices being all put in communication with one another. The many advantages that telephones have over speaking tubes both as regards range, efficiency, and ease in erection make it probable that installations of this description will multiply rapidly.

Canada. According to advices from Canada answers are expected daily from the various Governments of Australasia whether they will co-operate with Canada in surveying the route of the proposed inter-colonial cable between Canada, New Zealand, and Australia. Cheaper telegraphic communication with the mother country would be gained by the Australian colonies than they now possess if they embark in the proposed enterprise. We need not point out the immense interest these negotiations have for the Eastern and Eastern Extension Companies. The proposed lines are not wanted, but it is probable they will be laid, and, if we might assume the mantle of prophecy, we should say the above-named companies will, by hook or by

crook, themselves lay the cables when they see their competitors are determined to carry out the project. Negotiations may go on for some years, but in our belief the ending will be as we have said.

Buts Docks, Cardiff.—At these docks arrangements are being pushed forward whereby the West, East and Mouth Basins, together with the entrance locks, will in future be lighted by electricity instead of as at present by gas. Already the wires have been placed in position, and the erection is proceeding of a large engine-house in the vicinity of the Commercial Dry Dock, where will be laid down the necessary plant for providing the illuminating power. The adoption of the Brush system has been decided on and in all 20 lamps are to be hung, it being thought that these will suffice adequately to light up the large area over which they will be spread. Should the experiment be attended with satisfactory results, it is not improbable that in course of time the system of electric lighting will be extended until every portion of the docks is so illuminated. It is not, however, intended to remove the existing gas lamps even in the case of the ground marked out for the new departure. These will always be kept ready for any emergency. The lighting is expected to be ready in February.

Coming Home to Roost. The nonsense that has been written and spoken about primary batteries, has given our contemporaries their opportunity. The *Journal of Gas Lighting* in its issue of December 27th, says: "Electricians have proved too much, and too often wrongly to be lightly credited now. Why, they have actually promised that their patrons should be able to obtain light for nothing, and make a profit into the bargain." Such promises are highly reprehensible when they are made, but we would respectfully say that no electrician has ever made such a promise; and that a broad distinction must be made between the promises of patentees and promoters, and those made by responsible electricians. The *Journal* we have referred to each week dishes up for its readers a most ludicrous article entitled, "Electric Lighting Memoranda," in which it is difficult to say whether animus or ignorance is most conspicuous. Of its lucubrations we can say, in its own words, "it is depressing to think of so much labour and genius being spent in vain."

A Hero of Science.—Under this title, Dr. J. B. Daly contributes a short paper to *The Welcome* on the story of the electric telegraph as embodied in the early struggles of Morse to get his invention introduced to the commercial world. The hardships Morse had to undergo will be understood by the following anecdote of Strother's. It seems Strother was a pupil of Morse, paid his dollars in advance, but owing to the non-arrival of a remittance the second quarter's money was delayed. One day Morse came in and said courtously: "'Well, Strother, my boy, how are we off for money?'" "Why, Professor, I am sorry to say I have been disappointed; but I expect a remittance next week." "Next week?" he repeated sully. "I shall be dead by that time." "Dead, sir?" "Yes; dead by starvation." I was distressed and astonished. I said hurriedly, "Would ten dollars be of any service?" "Ten dollars would save my life, that is all it would do." I paid the money, all that I had, and we dined together. It was a modest meal, but good; and after we had finished he said, "This is my first meal for twenty-four hours."

Reduction of Chlorates by Electrolysis. The

following is an abstract of a paper from the proceedings of the Chemical Society. The authors of the paper are Mr. C. H. Bothamley and G. R. Thompson. "When a solution of potassium chlorate is reduced by means of the zinc-copper couple, a portion of the reduced chloride is converted into zinc oxychloride, which is insoluble in water but readily soluble in dilute sulphuric acid. The quantity of oxychloride formed is greater the more concentrated the solution. In order to avoid the error due to this cause, the chlorate solution is heated with the couple for about one hour, and pure dilute sulphuric acid is then added until the zinc hydroxide and oxychloride just dissolve. The liquid is filtered, neutralised with calcium carbonate and titrated with silver nitrate. Thus modified, the method gives very accurate results; the solution should not contain more than 1.5 gram of potassium chlorate in 25 c.c., and should just cover the couple."

Electric Light in a Flour Mill.—The Rock Mills, Londonderry, belonging to Mr. G. K. Gilliland, have just been electrically lighted by the Gulcher Company. Mr. Shannon has had charge of this work. The installation consists of a Gulcher dynamo, eighty 20 c.p. glow lamps, and an arc lamp of 2,000 c.p., the latter being placed in a mill yard. The dynamo is fixed on a sliding bed on the top of a wall about 3ft. thick, and is encased in a dust proof box, to prevent the possibility of igniting the flour dust floating in the air by the sparks at the brushes. At full output the machine is capable of supplying 150 20 c.p. glow lamps. The whole of the wiring has been carried out under the Phoenix Office fire rules, and where the conductors are carried from the old mill to the new mill they are encased in earthenware pipes lined with asbestos, whilst in other places they are carried in wooden casing. All the fittings, switches, and fuses are dust proof, so as to guard against the possibility of igniting floating flour by sparks caused on breaking circuit. There is a fuse to every lamp and to every branch wire, as well as to the main leads, whilst switches are fitted to the main poles, branch wires, and to every two lamps.

Carbon as a Positive Element.—In reference to this question and to its very important economical bearings, Mr. Desmond Fitzgerald writes to point out that the difficulty is not in the oxidation of carbon by means of a fluid, nor even in its oxidation by a true electrolytic action. The only difficulty, according to his view, is in finding a cheap and effective negative element and depolarising agent. It is in fact of little use to utilise what is theoretically, and may be practically, the most economical positive element if a heavy expenditure is incurred in the negative element and its depolarisation. It may be said that in all primary batteries the efficiency of the negative element is a more difficult, if not a more important question than the selection of an efficient and economical positive element. In connection with the latter, the question of local action is also of great importance from an economical point of view. Probably these observations have been suggested by the considerations of the new carbon-consuming—and chlorate of potash consuming—battery of Mr. Willard E. Case, of which the E.M.F. is given as 1.25 volt.

Telephony in the Alps.—Telephonic apparatus has been installed with great success in the famous Hospice of

the Grand Saint Bernard. The Paris correspondent of the *Daily Telegraph* says:—Canon Bourgeois, Prior of the Great St. Bernard, took it into his learned head about twelve months ago that if telephone offices were organised at St. Remy, in the monastery itself, and at Prez in Valais, the number of fatal accidents annually happening among French and Italian workmen while crossing the mountains between October and May might be diminished. He communicated the idea to Canon Berard, of Aosta, who took up the matter with energy. M. Bourgeois had invented a telephonic apparatus of his own, and after a while the Swiss and Italian Governments gave their respective sanctions to the proposed plans. The Prior was duly authorised to join his telephone to the telegraph wire between Aosta and Martigny. Since then telephones have been in operation at La Thuile, in the Hospice of the Little St. Bernard, and in several adjacent cantons. Last Sunday the Canon had a kind of field-day with his telephones, and, making the Little St. Bernard his temporary headquarters, he conversed with the brother in charge of the office in the Hospice of the Grand St. Bernard and with the officials in the various cantons.

Gas v. Electricity.—A note appears in the last issue of the *Gas World*, which deserves attention. The papers devoted to gas interests never miss an opportunity of declaiming against electricity, and nothing seems to please them better than to chronicle a failure in electric lighting. The following is the note referred to:—Writing to us on the subject of gas and electric light, Messrs. Baxendale and Company, Manchester, say that some time ago Messrs. Hope Brothers, Ludgate Hill, London, opened an extensive branch establishment in the leading thoroughfare of Manchester. The nature of their business requiring a powerful outside light, they determined to fit up electric arc lamps the whole length of the building. This was done by one of the leading electric engineers in Manchester, but the uncertainty of the light and the loss of a man's time, who was kept constantly attending to the lamps, caused the firm to look out for a substitute which would require no attention, and which would yet give a powerful light. Gas replaced the arc lamps. Now we should be glad to have the electrical engineer's statement of his case. For our own part we are quite sure that there are half-a-dozen different arc lamps suitable for such work, that would burn quickly and effectively without the loss of "a man's time," except, of course, so far as the necessary trimming was concerned.

Electricity a Competitor with Gas. The *Gas World* in its retrospect of 1887, admits that electricity is and will be a competitor with gas for illuminating purposes. It says: "As the electric light does not appeal to the lower strata of society, and as it cannot be said to have any substantial claim upon the middle class, the advocates of that system of lighting must look for the greatest amount of support from the wealthy and aristocratic classes. And it is just in the houses of these people that gas is generally used. It will now be perceived that if the gas industry is to be injured, the injury must come from the adoption of the electric light in the better class of houses, places of public amusement, and restaurants, where hitherto gas has reigned supreme. It is clear, therefore, that the true competitor of gas—at least, for public and private illumination—is the arc and incandescent electric light. These systems have already supplanted gas at many large establishments in the metropolis and in the provinces. Some folks may think it

is paradoxical to assert that the gas industry is advancing while the incandescent electric light is ousting it from these establishments. But it is the case, all the same. Recent years have seen the application of gas to a variety of purposes undreamt of by the pioneers of the industry. It is the fuel in many instances which drives the engines to keep up the supply of electricity; it is used for domestic purposes, such as heating, cooking and washing."

Electric Light at Terni.—This installation of these works, says *Industria*, which has now been in use for about a year, has proved very successful. At first some difficulty was experienced with the arc lamps, which had a tendency to overheat, owing to the vibration caused by the blows of the 100-ton hammer, but some improvements have been made in the feeding mechanism, by which this difficulty has been successfully removed. An accident also happened a short time ago in the dynamo house, when one of the joints in the high pressure supply mains gave way and flooded the room very quickly, doing some damage to the electrical machinery. With these exceptions, however, the installation has worked without a hitch. There are about six miles of mains put up, chiefly copper wire, supported by porcelain insulators on poles. The lamps are divided into twelve circuits, which radiate in all directions from the clock tower surmounting the dynamo house, and each circuit is separately controlled by a switch. There are about one hundred Schuerl arc lamps of 2,000 c.p. each, and over three hundred Bernstein glow lamps of from 25 c.p. to 50 c.p. in use. The total area occupied by the steel works is 210,500 square yards. For external lighting, some fifty-six arc lamps illuminate an area of 160,000 square yards, being at the rate of one arc light for every 2,860 square yards, whilst for internal lighting there are forty three arc lamps which illuminate an area of 31,500 square yards; thus each lamp lights 730 square yards. The incandescent lamps are distributed over an area of 4,000 square yards.

New Year's Honours. The *Evening Post*, discussing the honours announced with the new year, refers to that bestowed on Mr. John Pender in the following terms:—"Sir John Pender" long looked for, come at last. The ex member for the Wick Burghs has found it easier to get a knighthood from a Conservative Government when he is out of Parliament than to be decorated by his own party when he was serving it by his votes. But the belief is that Sir John Pender, K.C.M.G., rated his services to the country at something higher than the second grade of a Colonial order. Whatever be the opinion of the *Evening Post*, whatever be our opinion of Mr. Pender personally, there can scarcely be two opinions as to the services he has rendered, in conjunction with his colleagues to this country, and we deliberately say that the distinction conferred upon him is unworthy of the country he has delighted to serve. It may be all very well to say, since his and his colleagues' policy has been successful, that any other man would have been just as successful. We deny it. The battle has been fought and won—any man can now rest on the battlefield and shout victory—but that is no proof of his being able to win a victory himself. To carry out a cable or any other system which has been constructed *ad hoc*, and is now approaching completion, is not a hard task. The uphill work was in past years, and it matters little whether the ruling passion was self-interest—which is the case with most of us—the result is of immense importance to the country and to civilized humanity, and if it deserved recognition, it deserves

something of a far higher order and character than has been given.

Telephony in the United Kingdom. A series of articles upon the Telephone Companies of the United Kingdom, which originally appeared in the *Weekly Bulletin* have been reprinted and issued in pamphlet form with an introduction by Mr. C. L. W. Fitzgerald. It may therefore be taken as almost an authoritative statement of the position of the telephone companies; and the remarks concerning the existing relations between these companies and the Government are worthy of attention. The most important paragraphs in this direction are at the end of the introduction and at the end of the reprint. Mr. Fitzgerald at the conclusion of his introduction says: "If a map were made of the different trunk wires already run by the various companies, it would be found that but little remained to be done beyond the running of trunk wires between London and Bristol and London and Birmingham to enable the principal commercial centres to converse together. Once this is done, the Postmaster-General will find a sharp competition spring up, against which he will find himself powerless." The concluding paragraph in the pamphlet reads thus: "The brief description we have attempted during the last few weeks of the development of telephony all over the United Kingdom has far exceeded the limits we proposed to ourselves when we set out; but as we went on the conviction was forced upon us more and more that public opinion needed to be informed of the magnitude of the monopoly silently growing up in all directions, and for which every year's delay in State purchase will add an increased burden to the country ultimately. There are a good many of our legislators who are only hailing to find a cause in which they may distinguish themselves. We commend to them the serious study of the telephone problem. Judging by past experience, the Government will need a good deal of awakening before it rubs its eyes and realises the naked fact that every year the sum which it will eventually cost the country to secure the control of the telephone service, which means cheap telephony and universal telephony, such as private companies can obviously never give, is mounting up at the rate of millions a year. The estimated value of the parent and subsidiary companies is now five millions sterling, and in a very few years they will have reached a value of nearer twenty millions than five. We suppose, however, that the Government will wait till the provinces are all connected with London, and the companies amalgamated, and at a enormous cost they will then begin to bestir themselves. Let us hope that in this case, at any rate, we may prove to be false prophets."

Gas Companies and Electric Lighting. The action of the Bradford Corporation (the owners of the gas works), of the Imperial Continental Gas Association, of the town of Lübeck, of the authorities at Londonderry, Waterford, &c., should be carefully considered by all engaged in the electric light industry. It would seem that the natural development of electric lighting is that the installations should be carried out by local companies specially formed to supply illuminants. Some years ago the present writer suggested to the gas companies that the best policy they could pursue was to obtain powers to carry

out electric lighting, not with any idea of never using those powers, but on the contrary, with the intention of pushing forward the work. Mr. King, from a paper read before the American Gaslight Association, seems to share these views. He says: "I do not believe that electricity is to drive gas for illumination out of the field, and that we can be comforted by knowing that our existing plant is to be devoted exclusively to sending out a fuel. But I do believe there is a place for electricity; that we, as gas men, are the proper ones to supply it, and that the time is coming when it will be so considered by all. There is a good deal of philosophy in the reply of a certain gas man, who was asked if it were true that his company were going to enter the electrical field? He replied: 'Yes, and I should not be surprised if we were selling coal oil before long. We are in the light business.' So far, the competition of electric light has not seemed to diminish the use of gas to any extent: in fact, most companies report not only the average, but even a larger increase than usual in their send out. But if the use of electricity continues to increase as it has in the last few years, will this always be true? In our section of country the arc light has almost superseded gas for street illumination. All buildings in course of construction of any size or importance in the various cities of the country are being wired for incandescent lighting. The report comes that all manufacturing establishments supplying electric lighting material are far behind their orders. Does all this mean that, after six or seven years use, it has been found unprofitable to engage in electric lighting, or that the demand is growing less? Undoubtedly there have been failures and unprofitable investments in this field: but has it been the rule? I certainly have heard of no gas company that has tried the experiment and failed." The reader of the paper thus goes on to explain the advantages a gas company has in carrying out the work. "Now, let us see what advantages the average gas company may have: (1) I would say on cost of installation, the probability is that all companies can find the small piece of ground necessary on the property they own, and maybe sufficient room in their present buildings, by rearranging and economizing space. For necessary foundations, a grout made of old retorts, old firebricks, and refuse of various kinds broken to the proper size can be utilized with spent lime, which is almost as good as cement for this purpose. (2) The saving in expense of management cannot be questioned. That with the force necessarily a part of the gas plant fewer new men will be needed, must be apparent. (3) That gas companies have a certain amount of refuse, that would otherwise be waste, which can be used for fuel. For instance, coal dust, coke breeze, and more or less coke that can be secured by screening their cinders. All these we use on ordinary grate bars, with the help of a Parsons blower. If a furnace adapted more especially for this kind of fuel say, something something on the plan of our regenerative or recuperative furnaces were made to supply a battery of boilers, the expense for fuel might be reduced to a minimum. Burners for using oil and tar are also being perfected. Possibly when prices for tar are such as have obtained in many parts of the country during the last few years, it might be found profitable to make light of it. (1) who can realize the possibilities and the advantages that gas companies may have over all other competitors, when they shall be able to use for fuel, or directly in the engine, a gas that shall cost them but from 2 to 3 cents per 1000 cubic feet? This you know we are promised."

ELECTRICAL DISTRIBUTION BY TRANSFORMERS.

The great simplicity, low cost and high efficiency of the alternate current transformer are merits which have given this apparatus a dominant position in cases where electric energy has to be transmitted over long distances and distributed throughout a considerable area. It may be that the future will see a greater development of storage batteries, a cheapening of these appliances and an increase in their present low efficiency, averaging as it does only about 60 per cent., whereby it will be possible to light a district from a central station and a large number of sub-centres containing storage batteries. In this case would be secured two advantages not possessed by the alternating current system. In the first place the current supplied would be suitable for motive power and electrolytic purposes, and in the second place the supply of energy would not be so directly and immediately dependent upon the maintaining of machinery constantly in motion at the central station. But notwithstanding these obvious advantages the use of batteries is at present practically excluded from central station lighting owing to their high cost and low efficiency, whilst on the other hand the theoretically less perfect system of distribution by alternating currents and transformers is coming more and more into use. It is a significant fact that the utility of transformers is even recognised by those who may reasonably be supposed to have the greatest possible interest in the direct supply system. Thus the Thomson Houston Company in America have added the Westinghouse alternate current system to their original business, and with the most satisfactory results; the New York Edison Company have bought the Ziperowsky patents for transformers in order to be able to extend their area of supply; the Milan Edison Company have had Ganz machines and Ziperowsky transformers at work for a year and a half, and other Continental Companies are following suit. A large central station on the alternate current system has been established at Rome, another at Lucerne, and smaller stations in various continental towns have become a matter of ordinary occurrence. Here in England central station lighting has not been developed to anything like the extent prevailing in America or the Continent, but the only large central station, that in Bond Street, in London is on the alternate current system, and as our readers know, a similar station on a truly gigantic scale is projected for Deptford from which a great part of the City is to be supplied.

With these proofs of the vitality of the alternate current system before them, engineers need not hesitate to adopt it at once for central station work, notwithstanding the possibility that some better system might be devised in the future. Hesitation might be justified if there were any probability that an equally cheap continuous current system would be available within a short time, or if the change to the better system, when it becomes available, would involve the discarding of the whole of the alternate current plant. But there is as yet very little prospect that the first proposition will be realised; whilst, as regards the second, it is quite certain that the greater and more expensive part of the installation, viz., the motive power and the distributing plant, will be equally suitable for the continuous current system when the transition can be made. It might be objected that the present system of overhead primary wires as used in connection with transformers would be quite unsuitable for general distribution on the continuous current system. The answer is, that overhead wires are equally unsuitable for a general system of public supply by means of alternating currents and transformers. It is in this connection that the partisans of the alternate current system have hitherto made the mistake of generalising from isolated experiments. We remember that it was some years ago a favourite boast of one of the electricians on the staff of the original Company owning the Gaulard and Gibb's patents; that they could override the Electric Lighting Act by not making any use at all of the streets but simply stringing their primary mains overhead from posts fixed to the roofs of the houses, and therefore on private property, for which wayleave could always be obtained without troubling municipal or other authorities. As a matter of fact the whole of the distributing plant in connection with the

Bond Street central station consists of such wires, and as this installation has attained a considerable size, it might seem as if the boast of the early pioneer above mentioned could indeed be realised in actual practice. But consider how the present state of things has come about. The Bond Street Station was started principally with the object of supplying the Grosvenor Gallery with light. The venture was a success, and induced other establishments to apply for current. Shopkeepers here and there, then private houses, some restaurants and cafes, and a few theatres and other places of entertainment became customers. It was so easy and simple to add new subscribers to the list. All that was required was to string a new pair, or tap one of the existing pairs of overhead mains, and connect those with a transformer installed on the premises of the new subscriber. Owing to the high pressure the current can be carried to a considerable distance, and thus there seems to be hardly any limit to extension. But this is not a general system of supply. As long as isolated points at considerable distances apart have to be supplied, the overhead system is probably the only one which can be used with economy, whilst the general and very natural objection of the inhabitants to overhead wires can be overcome by the plea that after all, in any given spot, there are but few of such wires erected. But, imagine what state of things would exist if every house in a district had to be supplied in this fashion. Wires would grow to the size of heavy cables, disfiguring our streets and forming an ever present danger. It is tolerably certain that amongst the many hundreds of mains which would cross our streets in all possible directions there would be some which are imperfectly secured or are otherwise defective, and would, from time to time, fall to the ground with disastrous results to life and property. But apart from considerations of safety, the system would be too costly. Mr. Preese recently told the Institution of Civil Engineers that the yearly upkeep of an overhead circuit costs about £7 per mile. With heavy cables the expense would probably be much greater, to say nothing of the damage which a snowstorm like that of last year might do to the system. In view of all this, the advocates of the alternate current system must make up their minds to adopt underground mains if they would hope to establish a system of supply which should be really general, and as it would be obviously too costly, and in a measure also dangerous to connect the transformer of each subscriber directly with underground mains in the same way as is now done with the overhead wires, we are forced to the conclusion that the distribution must be made by a network of low pressure underground mains, very much in the same manner, but not to the same extent, as the system at present in use where the lamps are directly supplied from the dynamos at the central station. We say, "not to the same extent," because the maximum distance from the source of current to the lamps could be considerably shortened. In the direct supply system, such as is used in New York, Berlin, Milan, and other towns, the source of current is necessarily concentrated at the central station, and although we may diminish the inequality of pressure at different points by the establishment of "feeding centres" each supplied with current at constant pressure by its own dynamo, there is obviously a limit to the number of feeding centres by the greater complexity of the plant at the central station, and by the necessity from economic reasons of employing dynamos of fairly large size. Each feeding centre must, therefore, supply a comparatively large number of lamps, and as a necessary consequence the distance between neighbouring feeding centres must be considerable, necessitating the employment of very heavy distributing mains. Now, if we can halve the distance between the feeding centres, we quarter the weight of copper in the mains, and it is in this connection that the great utility of the alternate current system, or for the matter of that, any transforming system becomes apparent. There is practically no limit to the number of feeding centres, or as they properly ought to be called, sub-centres, which can be installed. Owing to the high pressure in the primary circuit the feeding mains need not be large and yet the pressure at the sub-centres may be practically constant, notwithstanding any possible variation in the call for current at different times and in different sections of the district. It therefore becomes

possible to establish a great many more sub-centres as there are dynamos at the station, whilst the weight of copper in the distributing mains can be reduced to an amount which will render it possible to work the district with economy. But the present custom of placing a small transformer on the premises of each subscriber would have to be abandoned in a system of general supply. The installation would be somewhat as follows:—A network of underground distributing mains of comparatively small section and subscribers' connections as in the usual direct supply systems. The network to be provided with a large number of feeding boxes containing the connections with the secondary terminals of large transformers placed as near these points as possible. The primary terminals of these transformers would be connected by "feeders" also preferably placed underground, with the generating station. The loss of pressure in these feeders need only be very trifling, say from 1 to 2 per cent. at the outside, and since large transformers can be made almost completely self-regulating, the variation in pressure at the lamps could be kept well within the limits now usual in installations supplied on the direct system. In this manner it would be possible to light a considerable district from a station, two, three or more miles distant, but it is evident that this is only possible because of the proper network of underground distributing mains. Now this network would be equally necessary had we assumed that the district would be lighted by continuous currents with the intervention of storage batteries. The only part of the plant that would in this case have to be changed would be the alternate current transformers for which storage batteries would have to be substituted. Otherwise the whole of the distributing plant, including feeders, feeding boxes, network, and house connections, would remain serviceable under the new system. As regards the generating station the only part to be changed would be the dynamos, all the rest, viz., boilers, engines, shafting and other gear, regulating appliances, and measuring instruments, would be equally available when a transition to a continuous current supply can be made. To recapitulate, Secondary batteries would form the most reliable agents for distributing electric currents, throughout large districts from a central station, provided they were sufficiently cheap and efficient. Until batteries are improved so as to be able to compete in point of cost, maintenance and efficiency with transformers, it is best to supply the district on the alternating current system, laying down each power and distributing plant as will be equally available when the transition to the more perfect system of lighting by batteries can be made.

The secondary terminals of these transformers would evidently have to be coupled in parallel to the network of distributing mains so as to ensure automatically that distribution of current which involves a minimum of energy lost by the resistance of the mains. A moment's consideration will show that the primary terminals would also have to be connected in parallel with the source of supply at the central station. In other words the transformers must be run in parallel from a network of high pressure feeding mains. The only other alternative is to run them in series on a single feeding circuit, but there are several objections to this plan. In the first place there is the difficulty of regulation, and this we fear is insurmountable. It is true that attempts have been made to obtain self-regulation in a series transformers by inserting a small induction coil in lieu of every lamp switched out, so as to maintain the total current traversing to secondary coil of the transformer constant and independent of the number of lamps alight. But this device cannot possibly ensure constancy of pressure in the secondary circuit for the simple reason, that that portion of the secondary current which passes through the lamps is nearly a quarter phase in advance over that portion of the secondary current which passes through the coils. Consequently the maximum magnetisation of the core of the transformer must even with a constant resultant secondary and an absolutely constant primary current alter for every individual combination of lamps and induction coils and as the pressure is very nearly proportional to this magnetisation it follows that the brilliancy of the lamps cannot be a constant. This defect which is inherent in the series system might be overcome by the addition to each

transformer of some regulating device to automatically vary the number of the active primary turns, but as such an apparatus would involve the employment of more or less delicate machinery for actuating a complicated system of switches, it might almost be considered as impracticable. In the next place there is the objection to the series system that any failure at a single point in the feeding circuit would put the whole of the area served by the central station into darkness. In the parallel system a breakdown of one transformer would on the other hand only have the result of lowering by a very few volts the pressure on the lamps nearest to this particular transformer, the other transformers on either side of it being able to supply the additional current required. Another objection to the series system is that the section of the wire in the primary coil becomes too great, and the wire becomes therefore liable to be traversed by eddy currents. It is evident that in a general scheme of supply it will not be safe to employ currents of higher electro-motive force than 2,000 or 3,000 volts. We have lately heard about a proposal to go up to 10,000 volts, but until actual practice has shown this to be possible and safe electrical engineers will scarcely care to work at so high a pressure. Taking 2,500 volts as a safe maximum of pressure, an installation for the supply of 20,000 glow lamps simultaneously alight would require a primary current of 500 amperes. The cross sectional area of the wire in the primary coil of the transformers would therefore have to be very large, probably half a square inch, and with so large a section eddy currents would be almost inevitable. With parallel transformers no such difficulty would arise. The transformers would be fairly large, say from 500 to 1,000 lights, they would be practically self-regulating, and requiring no attention could be placed in underground localities for which a very moderate rent only need be paid. When storage batteries have become sufficiently improved they could be installed in lieu of the transformers and the transition to the more perfect system of a general supply of current for lighting, power and chemical purposes could be effected at a very moderate additional outlay. We have in the foregoing brief sketch necessarily omitted to consider many questions of detail, as a thorough consideration of the points involved would be far beyond the limits at our disposal. We have endeavoured to lay before our readers what may be described as the fundamental principles of distribution rather than a scheme worked out in all its details, but enough has probably been said to show that the means which are at present at the disposal of the electrical engineer enable him to lay down a system for the public supply of electricity for lighting purposes which will be safe, efficient and economical.

BUSINESS METHODS.

Complaints are frequently made by the trade that electrical Engineering does not progress so fast as, in the opinion of those engaged in it, it should. Various reasons are given for this. Now, it is the Electric Lighting Act which discourages enterprise. Then, it is the holders of some electrical monopoly, who imagine that the experience of the rest of the business world is to be reversed in their favour, and that the whole body of consumers are to fall down and worship, or come and be taxed as the monopolists may decree; other causes, no doubt will have been mentioned in the hearing of readers of this journal; but it is doubtful if one cause, which is probably more powerful for evil than any other is ever mentioned, viz. the method of carrying on their business adopted by many of those engaged in electrical industries. While quite able to see the folly of short sighted monopolists, many of those engaged in the manufacture, the sale, or the installation of electrical apparatus appear to assume just as great an inversion of the laws upon which business is usually transacted as do those upon whom they sit in judgment. They constantly act as though they expected the miracle Mahomet promised to his followers, to be performed for their benefit, and they have not Mahomet's sense, in too many instances, to go to the mountain when they find it will not come to them. In other words, they are constantly

expecting that in place of adapting their apparatus as closely as possible to the requirements of society as at present constituted, and gradually educating society up to a higher standard and a higher appreciation of their apparatus, society is to shut its eyes and open its mouth to see what a good fairy will send.

If they fix apparatus, in a great many instances they carefully withhold all information as to its construction, regulation, &c., from the users. If they are sellers of apparatus only, they expect the whole profit that can possibly be made on the transaction—that is to say, the whole difference between manufacturing cost and selling price; and they do not expect to assume any responsibility, to have any trouble, or to take any pains to make an apparatus go right. In many cases they do not know how to. It may be the tightening of a screw, the connection of a wire, the repairing of some one of those trivial slips that are constantly occurring and will always occur in manufacturing until a superior order of beings take to the work; and the maker may be hundreds of miles away, nevertheless, he or his representative has to come at the bidding of the seller, often at a heavy expense, to perform some trifling operation which, if it occurred in any other branch of engineering, would be cheerfully and promptly done by the user; and the reward for all this is a future profit, which from the nature of things, can hardly ever be realised. Or it may be that the installer himself has made a trifling error, as installers even will do *occasionally*, or something has occurred to some other part of the apparatus, producing results that he does not understand, and he promptly lays it at the door of some part of the apparatus that he has purchased, and that he likewise does not understand, having arrived at the cause by the simple process of reasoning adopted by the little boy who wished his grandmother dead, but who did not wish to say so straight out. It is not this and it is not that—at least, the installer *believes not*; it cannot be the other, because it is his own design; therefore, it must be that other apparatus that he bought from so-and-so; and, for their own credit, they had better send someone to see about it. It would be much better for them to spend a little money now than lose future orders.

And then if a firm happens to do business anywhere in the provinces, getting, as they usually do, a thorough business training if they hold on long enough; their experience with many firms who wish to supply their wants, or to whom they have to look for different apparatus that they use, are somewhat exasperating. They are usually inundated with circulars, often with beautifully illustrated catalogues, and occasionally honoured by the visit of a traveller.

In the course of their business they are perhaps requested to prepare an estimate for certain work for someone in their district to whom they are well known. They are perhaps entrusted with a contract to supply and fix certain apparatus, in which may be included some of the beautiful designs in the catalogues that have been showered on them. They place their orders for the different apparatus they require with the different makers. So long as these are outside the boundary of electrical engineering pure and simple they have no trouble. Orders are acknowledged, and the goods forwarded in due course. But immediately their requirements come inside the magic line, it is another matter altogether. The order remains unnoticed perhaps for days. Soon they write to know when they may expect the goods, as they want to start the installation. No reply. They write again, asking for a reply to their former letter. Still no reply. They telegraph. No reply. They telegraph and pay for a reply. Occasionally this produces some effect. They perhaps receive a reply that the order is in hand. Sometimes they are asked to refer to their order and the matter shall be attended to. Sometimes they get no reply at all. Meanwhile work is going on, and cannot be left. Perhaps a postcard is sent, and not unfrequently receives more attention than all the letters and telegrams.

Next contract, another firm is tried, sometimes with temporarily better results. Often a sample order for stores required in the lighting season is delivered in the following summer. In some cases an enquiry is booked as an order, though if it was made firm there would be the same

difficulty in obtaining delivery as before. Not infrequently samples of certain goods are sent, and, when the order is completed, the bulk are quite different. An order will be accepted conditional on delivery within say seven or ten days, but no effort is made to complete in less than three weeks, no matter what the conditions, and then it is considered sharp.

And as to how all this affects the trade. It must be remembered that all these delays cost money, and that in preparing his next estimate, the provincial engineer adds to his quantities a sum that will cover this extra expense, and reckons his profit on the gross total: so that in place of prices falling as they should do, with the progress that is constantly being made, the legitimate fall is seriously retarded without anyone benefitting, and with the result that fewer contracts are given out. Those who wait until prices reach a certain figure, go on waiting a little longer, whereas but for this unnecessary increased cost, many of them would have placed their orders. Or perhaps the provincial resolves to take the bull by the horns and make the apparatus himself in his own workshop, and so is gradually developed a rival who in course of time may not be satisfied with supplying his own wants. In any case trade is lost to those who held it before.

Another very reprehensible plan is that, adopted by many makers of apparatus, of giving to consumers the same terms as to the trade. A manufacturer has, say, a speciality upon which he allows a certain profit to the trade for selling. An installer, or a firm who make it their business to retail apparatus, bring this speciality under the notice of some clients of theirs and procure orders. By and bye, one of their clients, being perhaps interested in the science, takes up an electrical paper, sees the speciality advertised, writes to the advertiser, and in many cases receives a quotation at exactly the same figure as that at which the maker supplies to the trade; amongst them the firm from whom the enquirer has previously bought. The result is that the enquirer, if he be engaged in business, not understanding such an arrangement, comes to the conclusion that the firm he purchased from have been making an extravagant profit. That is to say, he takes it that their profit is measured, not by the discount the manufacturer has offered to allow him, less perhaps two carriages, packing, &c.; nothing will make him believe that, but by that, plus another trade discount, and he forthwith looks with considerable suspicion upon all transactions for some time to come.

There can be very little doubt that this proceeding on the part of the manufacturer is both morally and commercially wrong.

The local sellers have in some form or other expended time and money in placing the particular speciality before their friends; and they have done it on the implied understanding that rules in all other cases, that they will be protected by the manufacturer from the consequences of an accident such as that described, by the simple straightforward plan of quoting to customers, customer's prices.

A man building a house for himself, unless he be a builder, will not be able to buy his bricks and mortar at builders' prices, no matter how big a man he may be in other respects. He may get a discount for quantity if he purchases a large quantity, or for cash if he pays cash, but these will be special discounts, and will represent a portion of the extra profit that the purchase of the large quantity or the cash payment enables the seller to make. A trade buyer would get the same discounts in addition to the regular selling profit.

And the result to the manufacturer is to throw his former client into the hands of one of his rivals, so that, though he has possibly gained one customer, at no greater profit than before, he has lost the whole of his late client's connection; and he has converted him with all his local knowledge and influence into an enemy.

The above remarks are, of course, only intended to apply to those firms who carry on business on the lines indicated. There are, fortunately, many good electrical firms who conduct their business on sound business principles, with the usual result that success attends their labours, and that they go on extending year after year. On the other hand, there can be no doubt that business earned in the above

manner, affects even them in a small degree by causing outsiders to lose confidence in electrical engineering.

CONTINUOUS CURRENT TRANSFORMERS.

From one point of view the electrical engineer may take comfort to himself and rightly imagine that since '81 he may claim his work to be a great success, writ large; from another point of view this success may be questioned, and many quiet thinkers are inclined to spell success with an f. The truth is that we who live in these rapidly moving times are scarcely able to judge the exact position of things. If excel-sior is the watchword, who is to decide when the top

E.M.F. of the primary and secondary circuits. In working, the primary is the motor circuit, and the secondary, the generator circuit; and, as the current in one circuit is in opposite direction to that in the other, the effects of self-induction, Foucault currents due to the current in the armature and lead of brushes are neutralised, the one by the other.

The transformer exhibited at the late Newcastle Exhibition was a small one, being tested with an output of only 4 units, when only 3 per cent. of this was found to be required for driving, thus showing conversion efficiency of 97 per cent., the commercial efficiency came out at 86 per cent., the speed at 200. Improvements have been made in more recent machines; so that now, by running at a slightly higher speed, the electrical loss in large transformers, such as would be used in practice, is reduced

Fig. 1.—Section of Transformer.

of the mountain is reached. Every inventor is so enamoured of his own little child, that he fancies perfection is attained and nothing more is left for future workers. When Gaulard and Gibbs first introduced the transformer system into commercial circles, they met with scant praise, yet within a few years transformers have forced themselves into the front, and seem destined to be largely employed. Hitherto the majority of inventors, or rather patentees, have devoted their energies to alternate current transformers, but the defects are many, and the conveniences of a continuous current so great that attention has necessarily been directed to the designs of such machines. Several

to under 4 per cent.; and as the power absorbed in driving a large transformer would naturally form a smaller percentage than in a smaller one, a commercial efficiency of 94 per cent. can be confidently expected. "As there is some misconception as to what is the natural domain of the continuous current transformers, one of your contemporaries having just published a comparison between the cost of distribution, first, by accumulators; second, by continuous current transformers, and third, by alternate current transformers, we (Paris and Scott) take the opportunity of giving a sketch of what we believe to be the field and method of using continuous current transformers.

Fig. 2. Section of Transformer.

alternate current transformers are in the market, but, so far as we know, only one continuous current transformer, that which we now illustrate.

The continuous current transformer of Paris and Scott, consists simply of an armature, with two sets of conductors and two accumulators, revolving in a constant field, the field magnets being excited from the low tension circuit. The ratio of the number of turns in the one conductor on the armature to that of the other, is the ratio between the

One of their most important advantages over alternate current transformers is that they can be used in connection with accumulators. Another great advantage, that motive power can be distributed from the same central station, will come out in what follows by using a 600 volt high tension E.M.F. on the three wire system, and for lighting and small power, and transforming this into 100 volts, having accumulators in parallel with the lamps, these would discharge when the maximum output was required, and be recharged

when the demand was at a maximum, thus reducing the capital required for motive power, &c., at the central station. The advantages of having accumulators are so obvious that we need not recapitulate them. Not the least is that because of their admirable regulating qualities it is possible to take motive power from the same system that supplies light. Although motive power distribution by electricity has made little headway in England so far, yet we believe that in certain districts it will become before long more important and profitable than the lighting.

It is quite impracticable to distribute power up to 20 or

Fig. 3.

End View Transformer.

30 horse power with an E.M.F. of 100 or 200 volts, but with 600 volts on the three wire system it is quite practicable, large motors might be connected up between the two outer wires, when 35 horse power would only require a No. 8 wire. Where possible, the field magnets of the motor would be connected up to the low tension circuit, and where not the motor armature would have a small secondary circuit and commutator for exciting the field magnets. The motor would then run at practically a constant speed without any regulating appliances, they would require very little room and attention, and for this reason, even if the cost of electrical power came the same as power from gas or a steam engine, there would be few who would hesitate between them. The question is, can power be supplied as cheap or cheaper by electricity than it is obtained at present? Without going into figures the following figures will enable your readers to form an opinion for themselves.

It is acknowledged that for continuous work, except for small powers, a steam engine is cheaper and more satisfactory than a gas engine. Now, steam engines up to 20

Fig. 4.

Side View Transformer.

or 30 horse power, as they are usually worked, take from three to four times, and often more, as much coal per horse power as the large and well managed engines in a central station would require, besides which they each require a man to look after them, and a considerable quantity of oil, waste, &c., which items per horse power would, in a central station, be immensely reduced, so it is plain that, even with a loss of 30 per cent. between engine at the central station and the work to be done, power could be supplied at the same or less than it costs at present, leaving large margin for interest, &c., and profit, one very important point in the starting of an enterprise.

By thus combining the distribution of motive power with lighting from one central station the financial aspect of the whole affair is greatly altered for the better, for instead of the expensive machinery being only employed at its maximum for a few hours in the day, and for many hours doing very little or nothing, it is kept employed near its maximum for many hours, and by using accumulators almost continuously.

MAGNETIC INDUCTION, PERMEABILITY, AND SUSCEPTIBILITY.

BY E. C. RIMINGTON.

The definition of strength of magnetic field best conforming to the mathematical treatment of magnetism is "Strength of field is measured by the force with which unit pole is acted on when placed in that field." In treating magnetism from the more practical side, e.g., dynamo design, a more convenient definition is found to be "the number of lines of force passing through unit area measured on a surface normal to them;" or, if the field be not uniform, "the number of lines passing through an infinitely small area measured on an equipotential surface divided by the area." In order to make these two definitions agree, it is necessary to assume that a magnetic pole of strength m emits $4\pi m$ lines of force thus. Suppose round a pole of strength m a sphere of radius r to be described, and at any point on its surface a unit pole to be placed, the force acting in the latter will be $\frac{m}{r^2}$; hence, by the first definition, the strength of field at any point on the surface of the sphere is $\frac{m}{r^2}$; and, by the second definition, it follows that the number of lines passing through unit area of the surface of the sphere must be $\frac{m}{r^2}$, but the surface of a sphere $= 4\pi r^2$. Therefore, the total number of lines passing through the surface $= 4\pi r^2 \times \frac{m}{r^2} = 4\pi m$. Now, all the lines given out by the pole pass through the surface of the sphere, so that the pole gives out $4\pi m$ lines of force.

If a piece of iron be put into a magnetic field so that the lines of force pass through it, it becomes magnetised by induction and exhibits magnetic polarity. Its intensity of magnetisation is naturally defined to be its magnetic moment per unit volume, or $I = \frac{M}{V}$, where I is the intensity of magnetisation, M the magnetic moment, and V the volume. If the cross-section of the iron is constant throughout its length, the latter being measured in the direction of magnetisation, and we assume its poles to exist at its ends $I = \frac{m l}{A l} = \frac{m}{A}$ (A being the cross section), or $m = I A$, m being strength of pole, or, more correctly, strength of polar surface, as the poles cannot here be regarded as points.

If the strength of field in which the iron is placed be denoted by H , I is said to equal $k H$, where k is known as the "magnetic susceptibility" of the iron. k is not a constant depending only on the quality of the iron, as might be supposed, but is also a function of H , for weak fields; however, when the iron is now near saturation, k is more or less constant, but depends to a certain extent on the previous history of the iron as regards magnetisation. This system of writing $I = k H$, where k is a function of H , instead of at once putting $I = \phi(H)$, is conventional and artificial, but is the one generally adopted. It must be remembered that H is the strength of the magnetising field when the iron is in position, as this is in general different from the strength of that field before the iron is placed in it.

Suppose, now, a piece of iron of cross section A placed in a field, whose strength was h before the iron was put into

Fig. 1.

it. Let the intensity of magnetisation induced in the iron be I , its pole strength will be $I A$. Hence, $4\pi I A$ lines of force are emitted from the north-pole and pass, through

surrounding space, to the south-pole; these we will call external lines. Now, some of the surrounding space is occupied by the iron, let us suppose that n out of the $4\pi I A$ lines pass through the latter, this leaves $4\pi I A - n$ passing otherwise as in diagram. As every line of force is a closed curve passing externally from N to S and internally from S to N, the number of internal lines of force is $4\pi I A$, and these all pass through the substance of the iron from S to N. The total number of lines of force passing through the metal is thus: n external lines, $4\pi I A$ internal lines (these all being due to the iron acting as a magnet), and $h A$ lines due to the original field. These three systems of lines added vectorially give the resultant system, which is called the "total magnetic induction" in the iron. Suppose, for simplicity, that the directions of the three systems within the iron are parallel, then the total induction

= $4\pi I A - n + h A$.

The "magnetic induction" or B is the number of lines due to every cause within the iron per unit area, or

$$B = 4\pi I + \left(h - \frac{n}{A}\right) = 4\pi I + H.$$

H being the magnetising field which is less than h the original field by an amount $\frac{n}{A}$, this is due to the reaction of the poles on the field, and will be greater for a short, thick piece of iron than a long, thin one; if the length is infinite compared to the thickness $\frac{n}{A}$ will vanish and $H = h$, the same is true for an iron ring when the exciting field is due to a wrapping of wire conveying a current and completely surrounding it, since there will be no polarity. Since $I = h H$, $B = (4\pi + 1) H = \mu H$, where μ is known as the "magnetic permeability." Hence $\mu = 4\pi + 1$.

ELECTRIC LAMPS IN MINES.

BY J. W. SWAN.

Among the electrical memorabilia of the year 1887, the introduction of portable electric safety lamps for the regular lighting of coal mines ought to find a place.

It is long since the idea was proposed of applying electricity to the lighting of coal mines, but it is only since the incandescent lamp was perfected, and made on a miniature scale, that the idea became practically realisable. It was barely realisable even then, for a good deal of experimenting had to be gone through before the battery, necessary for supplying the power to light the lamp, was put in a practical form. Now, all the difficulties in connection both with the lamp and the battery have been overcome, and the portable electric safety lamp is in every actual-day use, to the number of over two thousand, in some of the most fiery mines in the kingdom. So far the result has been very satisfactory. Miners greatly prefer the new to the old ones, and this is not wonderful, when it is remembered that the electric lamps give four times the light of the displaced oil lamps. It is needless to say that there has been no explosion caused by the electric lamps; indeed, it is difficult to imagine how such an accident could possibly occur, for every point has been most carefully guarded—the battery terminals are inaccessible to the workman carrying the lamp, and the lamps themselves are thoroughly defended against injury.

The use of electric lamps instead of oil lamps in coal mines calls for new means in detecting the presence of fire-damp, for, of course, the electric lamp is unaffected by it. The old safety lamp did, to a certain extent, indicate the presence of fire-damp, but it did not indicate it soon enough; the air was already in a dangerous condition before the Davy lamp gave any sign, so that, independently of the new circumstances arising out of the substitution of electric lamps for oil lamps, a better and more sensitive indicator was urgently required. Fortunately, the electric safety lamp carries with it the power which enables this want to be met in an effectual way.

The idea of utilising the fact that a red hot platinum

wire glows more brightly in a mixture of air and fire-damp than in pure air, is due to Mr. Laveing, and he has worked out the idea very thoroughly, inasmuch that by means of his apparatus (which comprises the wires to be heated, a miniature photometer, and a small magneto-electric machine), comparatively accurate estimates may be made of the proportion of fire-damp present in air contaminated with it, down to so small a proportion of fire-damp as one volume in two hundred volumes of air.

The battery attached to the miner's electric lamp provides a ready means of heating platinum wire red hot, and by limiting the object of the test to detection without measurement, an exceedingly simple and small appendage to the electric safety lamp gives, on the principle described, even a greater power of detecting fire-damp than was possessed by the most sensitive of the oil safety lamps.

With a provision as that described for the detection of fire-damp, the electric safety lamp is not only safe in itself, but a means of safety by giving warning in the event of a dangerous accumulation of fire-damp occurring.

There is reason, therefore, to hope that the application of electricity to the lighting of mines, by means of portable lamps, an event belonging to 1887, will, by removing one of the causes of explosions, and by giving more light, tend to diminish the loss of life which unhappily attends the dangerous, but indispensable industry of coal mining.

Electric Clubs in America.—The electric club idea has evidently "caught on" in the States. Cincinnati is now about to follow in the footsteps of Boston, Chicago, and New York, and form a club of its own, where electrical men may forget trade rivalry and professional jealousies in the pleasures of social intercourse.

Curious Electrolytic Action.—No current meter as yet has found great favour with the profession on this side the water, but the Edison meter is extensively used in America. In a report by Mr. J. W. Hill to General Hickenlooper on the electric lighting of the central station at Chicago, reference is made to a curious action of these meters, about which, however, we should like a little more information. During the weighing of the zinc plates of the voltmeters used by the Electric Light Company to measure the amount of light furnished to the Depot Company, the phenomenon which, I am informed, is not infrequent was developed of the diminishing plate gaining instead of losing (as it should if the meter is working properly) in weight, showing an apparent reversal of current for certain meters. The custom in cases of this kind being (as I am informed) to take the gain in weight of the plates which should have lost in weight as the measure of zinc transferred. Although authorities on electrical science assert that, with a given strength of current, the rate of transfer of zinc from one plate to another in a voltmeter is constant for any given time, and knowing the time and current the loss of zinc by the positive plate may be calculated from constants determined by experiment, it seems strange that the current should be reversed, as it was in the meters noted above. And this fact, of which we have ocular evidence, would indicate a state of affairs very dangerous to the pocket of the consumer of light, for if these meters will work backwards (as it were), why should they not work forwards at a rate greater than that assigned by theory, and cause a registration of more light than it actually furnished? If I were a consumer of electric light, I should require better evidence than that before me now to induce me to accept the record of these meters as a reliable statement of the light furnished.

THE ELECTRICAL ENGINEER.

Published every Friday.

Price Threepence; Post Free, Threepence Halfpenny.

Editorial and Publishing Offices:

139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. Special Terms for a series can be arranged on application.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY, with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations, or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months	6 months	12 months
United Kingdom	3s. 3d.	6s. 6d.	13s. 6d.
Within the Postal Union	4s. 4d.	8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

TO OUR READERS.

Today this journal, which has hitherto gone through a somewhat chequered career, appears in a manner more befitting to the requirements of the times. In future it will be published each week. An effort has been made in this number to indicate the policy the paper will pursue, but just as it is impossible for the grocer or the draper to show all the good things in the window, so we are unable to do more than indicate the various matters which are intended to be discussed in our pages.

The tendency of the recent developments of electricity has been to prove that in its practical applications it must rank as a branch of engineering. In future an engineer, while possessing a general grasp of the whole subject of engineering, will have to specially qualify in one particular branch. Here indeed comes into force once more Lord Brougham's dictum, which in a modified form as applicable to engineers might read—the best educated engineer is "he who knows a little about all its branches and everything about one branch." While therefore devoting our pages specially to the subject of electrical engineering, we shall not neglect those subjects which have an indirect interest to the profession. Just as in other branches of the great engineering profession, we find electrical engineers are by the ordinary laws governing labour, gradually becoming classified into the grades of "Consulting," "Superintending or In Charge," "Manufacturing," and, the largest class "the workers." At present there is no broad line of demarcation between the various classes, but the time is fast coming when the distinctions will be more widely recognised. We trust that our pages will contain information necessary to each and all these branches of the profession.

The articles which appear in this number must be taken to indicate the drift of our policy, for we do not intend otherwise to lift the veil that the curious may see. Let us rather now consider the present position of electrical engineering. So far as electric lighting is concerned it is by no means new to the scientific public. From the beginning of the century the "arc" has been the wonder shown at all lectures on physics. In the forties for a time there was a boom in electric lighting almost as intense as that in eighty-two, but it died away because the embryonic dynamo could not take the place of primary batteries, and the latter were ill-adapted for the work required of them. In the fifties Wildes machine, and subsequently the Alliance machine, enabled the electric light to be used in a few lighthouses; but it was not till Gramme and Siemens gave to the world improved dynamos, that electric lighting was commercially practicable. The late Count du Moncel, the friend and the guide of the writer to the Paris International Exhibition of 1878, was enraptured with the development of electric lighting as shown by Jablochkoff; but it was reserved for the Paris Exhibition of 1881 to set the public mind in a blaze as to the possibilities of the new light. France, America, and a great part of England then lost their heads—the people lost their money, and electrical engineering in the broadest sense was started. Since 1881 the whirligig of change has been rapid, till now at the beginning of 1888, the certainty of what will constitute the feature of the immediate future is unsettled. We incline to the opinion that distribution by means of transformers will be tried on a large scale, and we believe that both alternate current and direct current transformers will be used. Whether transformers will ultimately give place to secondary batteries is a problem that time alone can solve. Certain it is that while there is an enormous field for the secondary batteries now in the market, great improvements must be made upon them before

they can economically compete with transformers in central station work.

Another branch of electrical engineering which promises immediate and great development is in the transmission of energy. It is true that electricians must learn to know the meaning of such words as "expedient," "convenient," &c. It is foolish to attempt to convert a user of power from steam to electricity when the former is as convenient as the latter. No matter how perfect the dynamo and motor, it stands to reason that one loss is better than three.

The present position then is, that we are in the initial stages of an enormous industry. The applications of electricity are so numerous that its possibilities seem almost infinite, and we intend from week to week to do our best to make our readers acquainted with those processes and constructions which seem to stand in the van of progress.

EDWARD GRAVES, ESQ.

PRESIDENT INSTITUTION OF ELECTRICAL ENGINEERS.

We have much pleasure in presenting to our prospective readers, with the first issue of *The Electrical Engineer* as a weekly paper, a portrait and a *fac simile* of the signature of the Engineer-in-Chief of the Post Office Telegraphs, who has recently been elected President of the Society of Telegraph-Engineers and Electricians—hereafter to be known, we believe, as the Institution of Electrical Engineers. This Society, for the last ten years, has had reason to appreciate the services of Mr. Graves in the capacity of its Treasurer; and the thirty-five years of practical acquaintance with electro-telegraphy to which that gentleman may lay claim constitute strong additional grounds for the honour they have sought to confer upon him. Mr. Graves represents the financial rather than the scientific side of electrical engineering; and it may here be pointed out that to him the country is mainly indebted for the reduction, to the extent of some millions sterling, of the compensation claims put forward by the various Railway Companies under the Telegraph Act. A glance at the list of the Past-Presidents of the above-mentioned Society will show that science can well afford a recognition of the claims of business industry and financial ability in the person of the actual President.

Mr. Edward Graves was born in 1834; and, as we have said, became first connected with telegraphy thirty-five years ago, when he entered the service of the Electric and International Telegraph Company. In 1856 he was appointed Superintendent and District Engineer of that Company's Northern District. It is not generally known that, from 1859 to 1863, Mr. Graves was a frequent and successful lecturer to popular audiences—greatly to the advantage of certain deserving charities. In 1870, the period of the transfer of the Telegraphs to the State—in which he was engaged in

the conduct of many of the chief arbitration cases—he was removed to Birmingham as Divisional Engineer in charge of the North-Western Division of Postal Telegraphs; and in 1878, on the retirement of Mr. R. S. Odley, he was appointed Engineer-in-Chief of the Post Office Telegraphs.

Mr. Graves represented the Post Office as delegate at the Paris Electrical Conference in 1881, when he received the Cross of Officer of the Legion of Honour from the French Government. He also served on the Channel Tunnel Defence Committee of 1882, and was a delegate to the Electrical Unit Conference at Paris in 1883.

GOVERNMENT AID TO TECHNICAL EDUCATION.

BY PROF. W. GARNETT.

Invited to furnish a short essay on the most striking object which has recently come under my notice, I was for some time in doubt what to write about, but during a few hours spent in London my doubts were dispelled, for, at the Apprenticeship Exhibition at the People's Palace, I saw what appeared to me to be more important from some points of view than any of the grand exhibits recently displayed in our numerous great exhibitions. I do not refer to the system of electric lighting there employed, nor, indeed, to anything of special interest to electricians, except, in so far as electricians and members of the medical profession must be interested, more, perhaps, than any other class of professional men in the work of scientific and technical colleges and institutes, for there are probably no other professions whose members owe so much to such institutions. The exhibit to which I refer is that of the work done by students of the Polytechnic Institution, and everyone interested in the education of artisans would do well not only to thoroughly study this exhibit, but to learn all that can be learned respecting the conduct of the Polytechnic classes, and the means by which such striking results have been brought about. A Bill for providing elementary technical education is to be brought before the House of Commons next session, and this time there is to be no power of veto given to the ratepayers as in the Bill of last session. It is worth considering whether the foundation in each district of an institution of the Polytechnic type would not prove a far more efficient means of developing technical skill in the country than the addition of workshops to board schools, and the placing of technical education in the hands of school boards and their elementary teachers under the superintendence of the Science and Art Department.

The Polytechnic Institution, or Young Men's Christian Institute, was purchased and equipped by Mr. Quatin Hogg some six or seven years ago, and has been carried on solely at his expense. Its membership is so far restricted that 80 per cent. at least of its members must be artisans. To gain any idea of the provision made for the recreation, education, and, we may add, religious instruction, of the members and students the reader must visit the institution and see everything for himself. No less than 6,000 young men are at present profiting by Mr. Quatin Hogg's liberality, and of these 4,000 are attending classes of one sort or another.

The annual cost is a little over £6,000, so that the advantages of the establishment are afforded at a cost only slightly exceeding £1 per head per annum. Of course the workshop classes cost a very great deal more than those in which the teacher requires only black-board and chalk, with, perhaps, a few diagrams, or even those in which chemical apparatus and reagents, or optical or electrical instruments have to be employed for purposes of demonstration, and it is clear that apprentices could not be taught to carry out such work as that exhibited at the People's Palace at anything like the cost above mentioned, but the whole expense of the workshop classes is included in the

average of £1 per head, and there is scarcely any comparison to be made between the cost of the technical teaching provided in Regent street, and that at which the work is done by some Continental schools which have recently been highly praised.

Technical education is at present a phrase to conjure with. The Government has made up its mind to do something to encourage and support it. Those who have the control of public and corporate funds are seeking how they can best employ them in promoting it. Private munificence is ready to endow it while literary and purely scientific education is placed for the time in the background. Notwithstanding this eagerness it is scarcely possible to find three persons casually brought together who will agree respecting what technical education should be, and what it is that should be thus endowed. In fact different trades have very different requirements, and even the same trade will require great diversity in its mode of treatment in different parts of the country. This makes it very difficult for any Government department to provide a scheme of technical education applicable to the whole country unless great latitude is given for its adaptation to the requirements of the various trades in different localities. For example, at a meeting of master plumbers held in the north of England the question was raised whether workshop practice should be part of the school curriculum for apprentices, or whether the training afforded in the workshops was sufficient. One master explained that, owing to the peculiarity of his business, many of his apprentices spent their time in "burning lead" in sulphuric acid chambers and had no opportunity of learning other branches of the trade. The business of another lay almost entirely in connection with domestic work and his apprentices had little opportunity of learning to make burnt joints. The result was a unanimous vote from the trade in favour of providing a workshop and practical instruction in all branches for the members of the technical classes. This, then, was the decision of the trade in that district, and it must be supposed that the master plumbers knew more of the requirements of their apprentices and the shortcomings of their own establishments than any College Council or Government Department could possibly know. Of course it was arranged to supplement the workshop practice by lectures and classes on arithmetic and mensuration, mechanics, the elements of physics and chemistry, including the effects of heat and cold on metals and water, and the chemistry of iron, lead, tin, zinc, copper, white lead, red lead, &c., the action of fluxes in soldering, the elements of hygiene, and principles of sanitation. In the same district the almost unanimous opinion of engineers (masters, foremen and draughtsmen) is, that technical training for their apprentices should, in the schools, be limited to laboratory work, and to the scientific basis of engineering (mathematics, mechanics, physics, chemistry, metallurgy, &c.), including, however, mechanical drawing, while for advanced students the laboratory work should comprise the testing of materials and experiments with steam engines and boilers, but the teaching of the use of tools should be absolutely confined to the worker, the technical school or college being provided with such tools only as are necessary for the work of the laboratory or the equipment of the museum and lecture room. They consider that in manual training the discipline of the workshop is of paramount importance, and there is much to be said for this view, although the extreme specialization which now takes place in very large works tends to develop, from the ordinary apprentice, men who can take charge of one tool and of one tool only. The writer met with a man out of employment a few days ago who had been for some years in a very large works, and was part of a drilling machine. There was no other machine in the works that he knew anything about.

It appears then, that as soon as we approach the teaching of specific trades, if we are to secure the confidence and support of masters and men, we must allow each trade in each district to decide for itself how its technical classes are to be conducted. In fact the workshop at the technical school will have simply to supply the deficiencies of trade workshops where such deficiencies exist, and under these circumstances it is not unreasonable to expect that where

the trade of a district determines that workshop teaching should be provided to make up for the imperfect training afforded to apprentices in the works, the trade will find the means of conducting such workshop classes, and thus prevent local or imperial funds being employed for the benefit of one particular trade in preference to another. The whole question of workshop practice is a trade question simply, for where trades unions are strong, it is useless to think of teaching trades to outsiders unless we are prepared to receive outsiders only into the classes. The remarks respecting the maintenance of workshops in technical schools apply equally to lectures and classes bearing upon the technical details of specific trades. Such teaching should be supported either by the particular trades, or by local charities, or corporate funds applicable to such trades, and not by imperial taxes or local rates.

But with respect to those subjects which form the scientific basis of all arts and industries, and most of which are included in the syllabus of the Science and Art Department, the case is different. By granting Government aid to the teaching of these subjects all trades have an opportunity of sharing in the benefit in proportion to the number of workmen engaged. The Science and Art Department, by its system of payment by results, already does very much of what is wanted in this direction, but it is necessary to extend Government aid both above and below the class of students now attending Science and Art Classes. In the higher branches of scientific and technical teaching, such as should be undertaken by University Colleges, the system of payment by examination results is altogether unsatisfactory. Such teaching must be adapted to the special requirements of the class, and in any one session must cover a very limited range, if it is to be efficient and thorough. It is therefore impossible that it should be given in accordance with a syllabus issued by the central authority, and covering the whole range of a "subject." If there are to be examinations to test such work they must, like those following University Extension Lectures, be based entirely on the syllabus of the teacher, but it is better that aid to such classes should be given upon the number of students attending and the general character of the teaching and appliances provided. A definite sum annually contributed to each institution would be the most suitable form of grant, and its due administration might be guaranteed by nominees of the Government being placed upon the governing body as in the case of the Welsh Colleges.

But while we have to provide for one stage of teaching above the Government science and art classes, there are at least two stages to be considered below them. In the first place there are the elementary schools which provide the only compulsory education which a child has to undergo. Here the foundations of a technical training should be laid, and we would revise the rule and train the teachers in such a way as to bring the teaching more into harmony with the life of the children. Kindergarten methods, for instance, might be adapted to the teaching of science in the higher classes, and instead of training children for the Stock Exchange when they are never likely to have £5 to invest, the time now devoted to stocks and shares and compound interest would be better expended upon workshop arithmetic, such as the calculation of the areas, volumes, weights, &c., of simple surfaces and solids. Drawing should have a very prominent place in the school curriculum and calisthenics should be encouraged in all classes, and not in the infants' school alone. The training of the eye and hand to work with tools other than drawing instruments, by the teaching of modelling or wood carving or other art handicraft work, which can scarcely be regarded as a trade, should be encouraged in the upper classes by a grant based on the inspectors' report.

But when the child leaves school at 12 or 13 he is too young to profit by the Government Science Class, where he must be trained to earn a grant by examination, and yet it is of vital importance that his education should be continued. Here the recreative evening class supplies the need, but at present these classes are sadly crippled by the conditions under which a grant can be earned for them. Except in London it has been almost impossible to conduct recreative classes successfully, for, while the attendance is of necessity voluntary, the child on entering the school usually

finds that he is obliged to go back to one of the standards which he passed in the day school and again study the three R's in order to earn a grant. The teaching in the evening schools should be scientific, technical, and recreative, and the three R's should be taught incidentally only. For example, if a boy is learning experimental mechanics he will be expected to work out a few numerical examples, and write out the answers to certain questions, and the same will be the case if he is allowed to make experiments for himself. Here is an opportunity of teaching him arithmetic, writing, and spelling, and he will learn these subjects in connection with others in which he takes a real interest, and the direct application of which to his trade it is easy for him to see. Drawing, carving, and modelling should be taught in these schools, but no attempt should be made to teach a trade as such. To make it possible to conduct classes of this description successfully, the children must feel that they are not being manipulated in order to earn a grant by an examination, and Government aid should be given on the inspector's report of the attendance and general character of the teaching, or if there must be an examination it should be in the "specific subjects" taught, and not in the three R's, while the main portion of the grant should be given for attendance, but drawing and modelling should receive no inconsiderable portion. When the boy is 15 or 16 he may be willing to study science in a more serious manner, and in the Government science classes he will again be encouraged to work directly for examination results.

To summarise the whole, it seems that the requirements of the country in technical education would be met by

1. Modifying the ordinary teaching in the primary schools so as to bring it more into harmony with workshop requirements.

2. Abolishing the three R's from the evening combination schools so as to make the teaching given in them sufficiently attractive to draw voluntary profits and giving liberal grants for "recreative subjects."

3. Encouraging the formation of such institutions as the Polytechnic (which might in some cases be connected with university colleges) in which the science and art classes should receive aid from South Kensington, while the trade classes are supported by the trades of the district aided by such charities or corporate funds as may be available for the purpose.

4. Subsidising by an annual grant from the Treasury the scientific and higher technical teaching supplied by university colleges and similar institutions.

In the event of institutions being founded similar to the Polytechnic in districts where no local endowments are available, contributions to the building fund should be made by the Treasury to a much greater extent than the maximum of £1,000 now obtainable through the Science and Art Department.

The following notes of a system of State-aided technical education have been issued as a basis for discussion at a meeting of a provincial branch of the National Association for the Promotion of Technical Education. It is understood that in the third stage, as well as in the second stage, the whole of the teaching is given in the evening.

It appears necessary to consider four stages.

I. Primary schools.

II. Evening continuation schools.

III. Science and art classes, and apprenticeship schools.

IV. Higher technical and scientific education in university colleges.

1-1) In primary school, the teaching should be brought more into harmony with the requirements of the workshop.

(a) By modification of the code.

(b) By training some of the elementary teachers in part, at least, in university colleges instead of training colleges, so as to bring them in contact, during their training, with practical men, who are always to be found attending such classes.

(2) Freehand drawing, practical geometry, and mechanical drawing should be taught in the

primary school. In the upper classes, experimental mechanics and elementary physics, modelling, and wood carving should be added, the last two as recreative employments rather than trades. *The teaching of specific trades should not be attempted under school Boards.*

II. The evening continuation class being voluntary, but intended for boys between 12 and 15, must be made as attractive as possible. To this end,

(1) The three R's should not be taught as grant earning subjects in the evening schools, but only incidentally in connection with specific subjects.

(2) The grant should be given for attendance, and for "specific" and recreative subjects, including drawing, modelling, and carving, examination results being made subsidiary to the inspector's report on the character of the teaching.

(3) No specific trades should be taught.

With the evening continuation school, the functions of the School Board should terminate.

III. Boys should pass on to the third stage soon after 15 years of age. In this stage, the Government science and art classes, and the apprenticeship classes, should be carried on side by side, if possible, in the same building.

(1) Government aid should be given to science and art classes, as at present.

(2) Where a science and art school, and an apprenticeship school, are accommodated in the same building, the grant to the building fund should not be restricted to £1,000.

(3) The teaching of each specific trade, in the apprenticeship school, should be under the supervision of a committee, consisting mainly of members of that trade.

(4) Each trade should determine in each district whether the requirements of the locality demand a workshop and the holding of practical classes in that trade in the apprenticeship school.

(5) No State-aid should be granted at present towards the current expenses of teaching specific trades, but the contributions of the members of each trade should, when possible, be supplemented by local charities, under the direction of the Charity Commissioners and Trade Guilds, and other corporate bodies, should be encouraged to assist.

IV. In very large centres, a higher class of scientific and technical training should be provided for masters, managers, works chemists, and other responsible persons, by means of university colleges.

(1) State aid should be granted to such colleges in the form of an annual subsidy, the amount of which should depend upon the extent to which the equipment of the college is adapted to meet the requirements of the district.

(2) The due administration of this subsidy should be secured by the appointment of two nominees of the Government upon the executive council of the college.

(3) Payment should be made to university colleges by the Education Department on account of any elementary teachers who are being trained at such colleges on the same scale as payments are now made to training colleges (suitable deductions being made for board and lodging).

THE LATIMER-CLARK VOLTAIC STANDARD OF ELECTROMOTIVE FORCE.

BY DESMOND G. FITZGERALD.

When a few facts and data relating to it are understood by the user, the Clark cell is probably the most accurate as well as the most convenient standard of e.m.f. that has yet been devised. Essentially, it is a voltaic couple in which the negative element is mercury in contact with mercurous sulphate (Hg_2SO_4) made into a paste with a saturated solution of zinc sulphate, and in which the positive element is zinc (necessarily amalgamated) immersed in a saturated solution of zinc sulphate, which again is saturated with the nearly insoluble mercurous sulphate. The zinc is usually also in contact with the solid mercurous salt. It was first described, I believe, in a paper by Mr. Latimer Clark, read before the Royal Society in 1872, its e.m.f. as measured in the B.A. units by means of the electro-dynamometer constructed for the British Association Committee, and also by means of a sine galvanometer, being given as 1.457 volt at 15.5° Cent (60° Fah.).

But the question as to the value at the present time accepted for the e.m.f. of Clark's cell might be a somewhat puzzling one to many of the younger electricians for whom I am now writing. Of course the cell itself, made up in the same way at different periods, does not vary in E.M.F., nor is the abstract volt ever different from 10^9 absolute electro-magnetic centimeter gram second units of electromotive force. Moreover the experimental determination by Mr. Clark of the E.M.F. of his cell, in making which it was assumed that the B.A. unit of resistance issued in 1865 was a correct expression of the ohm, has been very closely verified by Lord Rayleigh, who, on the same assumption, found the value to be 1.453 volt. Again, the value of the abstract ohm is, and will always be, 10^9 absolute c.g.s. units of resistance. But the reason why the E.M.F. of Clark's cell, under certain given conditions is still in some measure a moot point is that electricians have been able, to obtain a closer approximation to accuracy in the material expression of the ohm in the form of a column of mercury or of a wire of a certain length and sectional area. It was in fact very soon found that the 1865 B.A. unit of resistance was defective, and lower in value than the true ohm. In the fifth report of the B.A. Committee on electrical standards, dated September, 1867, the value of the B.A. unit of resistance, based upon certain electro-thermal experiments of Joule in which 772 Manchester foot pounds were taken as the dynamic equivalent of the British thermal unit, was given as .9870 of the true ohm, whence the true ohm would be 1.0131 B.A. (1865) units. In the report of the same Committee, read at the Southport meeting of the Association in 1883, .9867 ohm is taken as the value of the B.A. unit; this being almost identical with the value (.9868 ohm) arrived at by Lord Rayleigh and Mrs. Sidgwick in the same year. According to this determination, the true ohm would be 1.0135 B.A. (1865) units (or 1.0134 B.A. units if the higher value for the latter be taken).

In a paper which was published in *The Electrician* for May 10, 1884, Lord Rayleigh intimated that the experimental determinations conducted by himself and Mr. Sidgwick at the Cavendish laboratory were not yet quite terminated, and defines the ampere current as that which deposits per hour 1.025 grams of silver. He observes that "When we were provided with means for the absolute measurement of currents, the determination of electromotive force ($E \div CR$) is a very simple matter if we assume a knowledge of absolute resistance. A galvanic cell is balanced against the known difference of potentials generated by a known current traversing a known resistance. The difficulty relates entirely to the preparation and definition of the standard cells." In the same paper, Lord Rayleigh states that "If we take the true value of the B.A. unit (of resistance) as .9867 ohms, 1.453 volt (the value found by this experimenter for the E.M.F. of Clark's cell at 15 per cent. on the assumption that the B.A. unit of resistance is correct) will be replaced by 1.434 volt."

It will be seen that the ratio of the old and new values for the E.M.F. of Clark's cell is the same as that of the old

and new values assumed for the B.A. unit of resistance, viz., 1 : .9867. This observation may tend to remove a difficulty which has been encountered by some—perhaps by many—electrical students in accounting for the fact that the new value assumed for the E.M.F. of Clark's cell is less than the value originally assumed. This difficulty or puzzle—amusing perhaps to the proficient, but productive of annoying mystification to the solitary learner—arises from a process of reasoning which ignores the fact that the value of a unit and that of a quantity expressed in terms of the unit vary inversely. It is argued that as the unit of resistance was too small and required to be increased, and as the unit of current ($C = \frac{E}{R}$) was taken as constant, therefore

the voltage of Clark's cell, if accurately determined on the assumption that the unit of resistance was correct, would also be too small and would require to be increased. Here the facts are lost sight of, that a given absolute resistance would be expressed by a lower value in true ohms than in B.A. units of resistance, and that a given absolute E.M.F. would be expressed by a lower value in true volts than in B.A. units of E.M.F. Of course the correct reasoning would be that, as the unit of resistance was too small and required to be increased, therefore the unit of E.M.F. was too small and required to be increased, and therefore also the value of the E.M.F. of Clark's cell, in terms of the augmented unit, would be diminished. My sympathy with learners in all their difficulties must be my excuse for referring to this little matter at what some might consider undue length.

By resolution of the International Conference on electrical units, adopted at their meeting at Paris in April, 1884, the legal ohm was defined as the resistance of a column of mercury 1 square millimetre in section and 106 centimetres in length at the temperature of melting ice. The length of the same mercury column which gives the nearest approximation hitherto obtained to the true ohm is 106.24 centimetres. Thus the legal volt would be .99774 of the true volt, and the true volt 1.00226 legal volt. And taking the E.M.F. of Clark's cell at 15° C. as 1.435 true volts—the value given by Lord Rayleigh in his paper "On the Clark Cell as a Standard of Electromotive Force," read in January, 1886—its E.M.F. in legal volts would be 1.438.

In the recently published paper by Sir W. Thomson "On the Application of the Deciampere or the Centiampere Balance to the determination of the Electromotive Forces of Voltaic Cells," the author states that "the results obtained for four Clark standard cells set up by Mr. J. T. Bottomley in March last were almost identical with one another, and gave 1.439 Rayleigh, or 1.442 legal volts at 11° C. The variation of the electromotive force of these cells with temperature has not yet been determined; but assuming the average value obtained for this variation by Lord Rayleigh, namely, a fall of .077 per cent per degree centigrade rise of temperature, and correcting to 15° C, we obtain slightly under 1.436 Rayleigh volts at that temperature. This result is interesting, as showing a difference of less than $\frac{1}{15}$ th per cent. from that obtained by Lord Rayleigh for similar cells, which was 1.435 at 15° C."

It would be satisfactory to note as a fact so close an agreement as the above between two high authorities: still more satisfactory is it to be able to suggest that the agreement is really considerably closer. It is with some diffidence, however, that I venture to point out that Sir W. Thomson's corrected value should be very slightly lower instead of slightly higher than the value 1.435 volt obtained by Lord Rayleigh. But it seems to me clear that the agreement as above has been arrived at through an arithmetical oversight, which has, somewhat unaccountably, hitherto escaped detection. The result has obviously been obtained by multiplying the rate of variation per unit (.00077, into the difference of temperatures, and subtracting the product (.00808) from 1.439, the remainder being 1.43092, or "slightly under 1.438." But to obtain the fall in 1.439 volt due to a rise of temperature of 4°, it is not merely four times the rate per unit, but this value multiplied into 1.439, which has to be subtracted from 1.439. The remainder is then 1.4345 instead of 1.4359, a lower instead of a higher value than that (1.435) obtained by

Lord Rayleigh; and the percentage difference is only '035 or less than $\frac{1}{30}$ th, instead of "less than $\frac{1}{10}$ th."

The result in any case justifies the conclusion that we may safely take 1.435 true volts, or 1.438 legal volts, as the normal E.M.F. of Clark's cell at 15° C., or 59° Fahr.

The formula given by Lord Rayleigh for the E.M.F. of a Clark's cell at a given temperature (t) is as follows:—

$$E = 1.435 \left\{ 1 - .00077(t - 15) \right\}.$$

For the benefit of the young learner, I will point out that this may take the form:

$$E = 1.435 - 1.435 \times .00077 \times (t - 15),$$

and that when $(t - 15)$ gives *minus* value its product with the second *minus* value is *plus*.

By the application of this formula, it will be found that the E.M.F. of Clark's cell at 11° C. should be 1.4394 volt, thus confirming in a striking manner the result given in the above extract from Sir W. Thomson's paper as having been obtained by direct experiment.

According to Profs. Ayton and Perry (see *The Electrician* for January 8, 1886, p. 168), the temperature variation amounts to about 1 per cent. diminution per 12° C. elevation of temperature, corresponding to a coefficient of .00083 in the above formula.

In regard to the causes which affect the normal E.M.F. of Clark's cell, the most frequent source of error is the occurrence of supersaturations in the zinc sulphate solution. Great attention has recently been given to this point by Messrs. Elliott Bros., who have found it necessary to adopt special precautions in order to obviate the diminution of E.M.F. arising from this cause. In the valuable paper by Lord Rayleigh already referred to, the undersaturation of the solution, resulting in an E.M.F. higher than the normal, is referred to, as well as the above, as a source of error. But for every cell in which I have observed the E.M.F. to be above the normal by reason of failure to saturate the fluid with zinc sulphate, I have found at least twenty in which the E.M.F. was too low by reason of supersaturation. Many cells were formerly made up with a paste produced by triturating crystals of sulphate of zinc, with moist mercurous sulphate in a mortar. Comparing a cell made up in this way with another in which the zinc solution was just saturated, I have found the former to be 1.7 per cent. below the normal, even before supersaturation proper—brought about by rise of temperature and gradual cooling—had occurred. When the solution is supersaturated the fall of E.M.F. below the normal may exceed 2 per cent.

When the cell is made up strictly in accordance with the following directions, extracted from Mr. Latimer Clark's original paper read before the Royal Society in 1872, supersaturation—the condition in which a fluid will deposit crystals if a crystal be dropped into it or if it be violently shaken—is very likely to occur through unduly prolonged heating to expell air. The opposite error of undersaturation is, in the given case, of course out of the question.

"The best method of forming this element is to dissolve pure zinc sulphate to saturation in boiling distilled water. When cool, the solution is poured off from the crystals and mixed to a thick paste with pure mercurous sulphate, which is again boiled to drive off any air; this paste is then poured on to the surface of the mercury previously heated in a suitable glass cell; a piece of pure zinc is then suspended in the paste, and the vessel may be advantageously sealed up with melted paraffin wax. Contact with the mercury may be made by means of a platinum wire passing down a glass tube cemented to the inside of the cell and dipping below the surface of the mercury, or more conveniently by a small external glass tube blown on to the cell, and opening into it close to the bottom."

It may here be pointed out that in the glass cells as usually made the external tube is not made to open into the cell sufficiently close to the bottom. An unnecessarily large quantity of mercury has therefore to be used, and the probable ill effect of any shaking or concussion of the shell is facilitated. Although paraffin fairly answers the purpose in view, it must be admitted that it cannot be depended upon for the hermetic closure of the cell. It frequently allows of the escape of fluid by capillarity; and, after a certain time, the E.M.F. falls about 2 per cent. below the normal by reason of the supersaturation of the solution and

the formation of crystals of zinc sulphate. Some steps have already been taken to remedy these shortcomings, the indication of which will doubtless have the effect of hastening improvement.

The importance of using pure materials in the construction of the cell need scarcely, one would think, be insisted upon at the present time. The mercury salt in perhaps most of the cells in use several years ago was of a yellow colour—this indicating that the mercurous or sub-salt was contaminated with the mercuric or per salt (HgSO_4); the latter becoming decomposed in presence of water into an acid salt and a basic salt of a yellow colour. That of the pure mercurous salt is a greyish white. The excess of acid in this salt, as usually prepared, may be removed by the addition of a little oxide or carbonate of zinc; but perhaps the best, though the most wasteful, method of purification, is copious washing with distilled water.

INSTITUTION OF CIVIL ENGINEERS OF IRELAND.

In the Inaugural Address of the President, Mr. John Purser Griffith, reference is frequently made to the part which electricity plays in engineering matters. The following paragraph shows a number of the uses in which engineers recognize the utility of electricity. Mr. Griffith said:

"I have referred to the safety with which we can travel on our railways. For this we are specially indebted to the electric telegraph, by which our block systems are controlled. Electrical engineering has now become an inseparable branch of our profession, and we are constantly calling electricity to our aid. Its application to telegraphy only dates back to 1837. The first line was laid under ground between Euston and Camden Town. The difficulty of maintaining the insulation led to the use of the unsightly poles and overhead wire with which we are so familiar. On the railways of England, Scotland, and Ireland, we have now over 69,000 miles of wire in use. But, perhaps, the most remarkable progress has been made in submarine telegraphy. Many of us can recall the attempt made to lay the first Atlantic cable. Now the land was filled with anxiety respecting the result, and what disappointment followed its failure! Now nine cables cross the Atlantic, and England is bound to other lands to China, India, Australia, New Zealand, and the Cape. More than 80,000 miles of submarine cables are now at work and by their success the ideas of time and distance upon which we were brought up have received rude shocks. Perhaps nothing has been more remarkable than the skill exhibited in increasing the capacity of these wires for the transmission of messages. In place of manual labour, by which 30 words per minute can be sent by a skilful operator, we now have a mechanism which will transmit 250 words per minute; and by the introduction of duplex and quadruplex telegraphy, two or four messages can be transmitted on one wire at the same time."

"Telegraphy is but one of the directions in which electricity is useful to the engineer. The telephone, as a time-saving instrument, is familiar to us all, and I need scarcely refer to it beyond remarking that but for the convenience of rapid communication it would be expelled from many an office as an unqualified nuisance and rude companion. There is one application of the telephone which has been of special value—that is, as a means of communication between divers and their attendants above water. Anyone who has experienced the sensation of finding his life-line and air-tube entangled while in deep water, will appreciate the advantages of such a means of communication. It has added much to the safety of diving operations, and facilitates the men's work. Electricity has also been applied with great success to blasting operations, superseding in large works the dangerous and uncertain fuse. The most successful instances of its use for this purpose have been in the removal of the reef at Hallett Point in the East River, New York, known as Hell Gate, and the Flood Rock. In the former explosion 4,427 separate charges were simultaneously fired, and a reef covering an area of 3 acres and containing 63,000 cubic yards of rock, was demolished. The Flood Rock, or Middle Reef, covered an area of 9 acres, and 270,717 cubic yards of rock were shattered by the explosion, which was successfully carried out on the 10th of October, 1885."

Considerable progress had been made in the utilization of electricity for the transmission of power from a distance. In Ireland we have two examples of electric railways at work—one from Portrush to the Giant's Causeway, the second from Newry to Rossbrook in County Down.

"In electric lighting the progress, though not as rapid as was expected some years since, has been very marked. The use of search lights on steamships has enabled vessels to be equipped to navigate the Suez Canal at night, and the passage through the Canal can now be accomplished in 16 hours instead of 36 hours. This, obviously, has added to the capacity of the Canal for the passage of shipping, and will probably postpone the necessity of a second canal for many years."

ENGINE ROOM SWITCH-BOARD.

DESIGNED BY W. H. MASSEY.

Of all the accessories of electric lighting a simple and effective switch-board is one of the most important. We herewith illustrate a simple form of engine room switch-board which has been designed by Mr. W. H. Massey. The switch-board is in use in several large installations, and has been designed with the object of enabling engine drivers and others in charge of electric lighting apparatus to see at a glance how the various circuits under their charge are coupled up. We have seen switch-boards that were wonders of ingenious contrivances, and turned away with the sad reflection that life was really too short to venture upon the study of their hidden mysteries. Mr. Massey's design

seen, are not shown in the illustration, but the connection is easily understood. Generally speaking, for night working, one pair of house mains is amply sufficient, but, on special occasions, such as when parties or balls are being given at large mansions, the service would be by the two-house mains, both engines, one on each circuit, being employed. On such an occasion the secondary battery may be used as a stand-by, or for giving the current to those lamps which are required to be burnt all night. Of course this is but a brief description of an apparatus for which there is many an arrangement. We have spoken of dynamos always in use with a secondary battery as a stand-by; of course this is not the case, as on Sundays, and frequently in summer, the engines might not be required to run at all during the day.

certainly cannot be said to err on the side of complexity, but may be acknowledged to be as he terms it, a simple switch board. All the connections are easily got at, and it is not necessary to remove a number of connections amounting in some instances to a considerable percentage of the whole board, in order to take out a pair of leads.

The board now illustrated is suitable for two dynamos giving 250 amperes each, and a set of secondary batteries of large dimensions. The connections are shown by the diagram, so that it is not necessary to enter into this detail. For the ordinary day-work of an installation one dynamo may be coupled to one set of house mains, if required, while the other is being used to charge the secondary batteries.

Separate volt and ammeters are placed in the battery circuit for use when the battery is discharging. These, as will be

PARIS AND SCOTT'S NEW C-TYPE DYNAMO.

In this machine, illustrated below, the conductor on the armature is wound in deep and narrow slots cut in the iron plate forming the armature core. The result of making the slots very narrow is that the noise and heating of the pole pieces usually produced in machines with toothed armatures are entirely absent, as the armature presents what is practically a continuous face to the pole pieces; and by making the slots very deep there is plenty of room for a large quantity of conductor to be wound on, and also for the especially good and thick insulation which is used, the makers considering that durability and freedom from risk of break-down are of first importance. Other considerations, however, have not been sacrificed, the magnetic resistance is low, and a field in the armature core of

23.6 Kapp units per square-inch sectional area is produced with a very small expenditure of power in the field magnets, so that the electrical efficiency is high, especially when the comparatively low speed 850 revolutions is taken into consideration.

The resistance of armature is . . .	0.29 ohms
" " magnets . . .	35 "
Loss in armature with 120 am. . .	317.5 watts
" magnets " 100 volts . .	286 "

Total electrical loss . . . 703.6

Showing an electrical efficiency of over 94 per cent.

The field magnets are of cast iron, by the use of which the cost of the machine is very much reduced. And although this cast iron is of great sectional area, being three times that of the iron in the armature core, yet the

behaviour of the leaves if without any other change in the apparatus the slab of the shellac is transferred from A to B 15

2 A kettle which can be held by an insulating handle is positively electrified, and water is poured from it into an insulated metal teapot. How are the electrical states of the kettle, water, teapot altered during the process? 20

3 How would you construct an electrophorus from which charges of negative electricity could be obtained? 10

4 Two small equal metal balls charged with equal quantities of positive electricity are placed at a fixed distance from each other. They are then touched in turn with an unelectrified insulated metal ball of the same size, which is not discharged between the two contacts. In what proportion will the force between two balls be diminished? 15

Division II.

5. If you were given a galvanic cell, wire, and a compass, how would you determine which was the positive pole of the cell? 10

Paris and Scott's Dynamo.

total weight of the machine illustrated, having an output of 12,000 watts at 850 revolutions, is only 1,268 lbs. Of this the armature complete weighs 147 lbs. Where lightness is important—as in some motors and in ship lighters—by using wrought iron for the field magnets the weight of machines with this type of armature is greatly reduced. The mechanical construction of these armatures makes them suitable for motors for tramcar and electric railway work: the plates forming armature core being made with a hexagon hole and threaded on to a hexagon shaft; so that each one is driven direct, and as the conductor is wound in slots in the plates the torque which the whole will stand is manifestly very great.

SCIENCE EXAMINATION IN TRAINING COLLEGES.

MAGNETISM AND ELECTRICITY.

The following examination paper was set for the purpose of testing the knowledge of our future schoolmasters in magnetism and electricity. We could almost imagine that the world had stood still during the past fifty years so far as this subject is concerned if these examination questions were any guidance to the present state of electrical knowledge. Surely it is time that those who control the examinations should insist upon some questions being given to test the student's familiarity with recent developments of the subject. How many electric light engineers could answer the questions, or would acknowledge that any one of them had a bearing upon the practical part of their work?

Division I.

1 Two gold leaf electroscope, A and B, are placed at a considerable distance apart, and an unelectrified slab of shellac is laid upon the cap of A. Two positively electrified balls are then brought near the caps of A and B respectively, and the electroscopes are for a moment connected with earth. Explain the

6 Three similar wires are joined together so as to form an equilateral triangle ABC. Two corners of the triangle, A and B, are joined to the poles of a battery. Will all three sides be equally heated by the current? Give reasons for your answer 15

7 An observer looking down upon a copper ring drops through it a bar magnet north-seeking end first. In what directions would the current produced in the ring appear to him to circulate (1) before, (2) during, (3) after, the passage of the magnet through the ring? 20

8 The resistance of a tangent galvanometer is 20 ohms, and a current passes through it which deflects the needle 60°. It is shunted by a certain resistance, and the resistance of the rest of the circuit is altered so that the total current is the same as before. If the needle is now deflected through 30°, what is the resistance of the shunt? 15

$$[N.B. \tan. 60^\circ = \sqrt{3}, \tan. 30^\circ = \frac{1}{\sqrt{3}}]$$

Division III.

9. A bar magnet is placed to the south of a compass, and in the magnetic meridian which passes through the centre of the compass needle. If the south-seeking end of the bar-magnet points north, explain the behaviour of the compass needle as the magnet is brought nearer to it. 10

10 An iron hoop is held in the plane of the magnetic meridian. Describe its magnetic state 15

11. The upper end of a dipping needle is weighted with wax until it will remain in any position in which it may be placed when free to move in a plane perpendicular to the magnetic meridian. Describe the effect (if any) of turning the instrument round so that the needle moves in the magnetic meridian. Give reasons for your answer. 20

12 A bar magnet and an iron rod are placed in the same straight line, and iron filings are strewn on a sheet of paper which is laid over them. Describe, with a sketch, the form of the curves assumed by the filings when the paper is tapped. 15

PORTABLE VOLTMETERS FOR MEASURING ALTERNATING POTENTIAL DIFFERENCES.

BY PROFESSORS W. K. AYRTON AND JOHN PERRY.

It is now well understood that a high-resistance electro-dynamometer cannot generally be used for measuring alternating potential differences, in consequence of the self-induction of the dynamometer causing the effective resistance—and therefore the sensibility—of the dynamometer to vary with the speed of alternation. Further, even for the measurement of direct potential differences an ordinary high-resistance voltmeter, employing the magnetic property of the current, is not entirely satisfactory if the forces employed be large (as they generally have to be in dead-beat portable instruments), since, in that case, the current, if kept continuously on, slowly heats the voltmeter, and by increasing its resistance causes its sensibility to diminish. It has, therefore, for some time seemed clear that the heating effect of a current should be used for voltmeters.

Captain Carlew was the first person to utilise this principle in the construction of voltmeters, and, as far as we are aware, is the only person who, up to the present time, has employed the extension of a wire, caused by the heating produced by the passage of a current, to measure the potential difference at its terminals. His instruments are well known, and have afforded most valuable aid in the measurement of alternating potential differences; and we, in common with other electrical engineers, owe him a debt of gratitude for providing us with the only commercial instrument that has existed for the measurement of alternating potential differences.

In "Practical Electricity" an attempt has been made to impartially sum up the advantages and disadvantages of all the more important ammeters and voltmeters, and we cannot do better than repeat what was there said about the Carlew voltmeter, especially as we understand that Captain Carlew considers the criticism to be a fair one.

"CARLEW VOLTMETER."

Advantages.—First, it has but a small heating error; second, the self-induction is negligible. It is also dead-beat, direct reading, not disturbed by magnets, and fairly portable, although large.

Disadvantages.—It absorbs a good deal of energy; second, it cannot be used for measuring a small potential difference, for we cannot make it of thicker wire, as we should do in the case of an ordinary voltmeter intended to measure small potential differences, as this would render it sluggish, since a thick wire traversed by a current heats and cools slowly on starting and stopping the current; third, there is considerable vagueness in the readings near the zero point, and sometimes inaccuracy in the upper parts of the scale.

Towards the end of 1885 we were engaged on certain experiments on the governing of transformers in series to give a constant potential difference at each house, and, as our experiments were to be conducted with small transformers, we required a voltmeter which would measure an alternating potential difference of three or four volts with accuracy. Such an instrument not being in the market, we were compelled to devise one; and we were led to consider whether the Carlew principle might not be employed in an instrument which should give quite definite readings even near the zero, and produce a large deflection when an alternating potential difference of a few volts was maintained between its terminals.

Part of the vagueness in the readings of the Carlew instrument we saw was due to the employment of toothed wheels; and, as explained in a paper* read by us before the Royal Society in 1894, toothed wheels have not recommended themselves to us as a means of magnification in ammeters and voltmeters, in consequence of the friction they are liable to introduce. In fact, after giving toothed gearing an extensive trial in our instruments, originally described to this Society† in 1882, we decided to abandon its use in 1884.

If a voltmeter depending for its action on the expansion of a wire by heating is to be sharp in its action, the wire must be fine, and if it is to measure a small potential difference the wire must be short; hence we were led to consider whether it was not possible to construct a voltmeter of quite a short length of fine wire, and observe its extension with some frictionless magnifying arrangement. This led us to consider the platinum wire telephone described by Mr. Preece in his paper‡ read before the Royal Society in 1880, which, although composed of but a short length of wire, evidenced by the motion of the diaphragm, to the centre of which one end of the wire was attached, every change in the current passing through it. After thinking out various means of attaining this result, we were led to see that one of our magnifying springs, described to this Society in 1882, fur-

nished the means of obtaining a sufficiently sensitive frictionless magnifying arrangement. For experiment shows that if a short piece of fine wire *W'W'* (Fig. 1) only seven inches long be

stretched between two supports *A* and *B* to which it is equally attached, and if it be pulled slightly out of the straight line by one of our right and left handed magnifying springs *M*, rapidly attached at its one end to the wire and at the other to a support *S*, the axes of the spring and the wire being at right angles to one another, the arrangement is so delicate that the expansion produced by even the approach of a warm hand is evidenced by the rotation of a pointer *P* attached to the centre of the right and left handed magnifying spring. The absence of all gearing and the rigid fastening of both ends of the spring, combined with the fineness of the wire, make the arrangement remarkably dead-beat in its action, and when the wire is enclosed in a short metal tube we have a voltmeter which will measure even the fraction of a volt, whether the potential difference be direct or alternating, since the readings even near the zero are quite definite.

The right and left handed spring was employed to avoid any twist being given to the wire, but one of our assistants, Mr. Bourne—who has worked at this instrument with his customary ingenuity and dexterity, soon found out that half the length of the spring could be dispensed with, and an equally efficient but much more compact arrangement could be effected by using a single ordinary magnifying spring *M* (Fig. 2) and introducing a

small piece of fine wire (*W'W'*) between the one end of the spring and the stretched wire *W'W'*, or between the other end of the spring and the support *S*.

To get extreme quickness of action on changing the potential difference, it is desirable to employ a thin wire; and as the strength of such a wire is small, the next step was to combine a number of wires mechanically in parallel, and electrically in series or parallel, the wires being attached at their middles to a stirrup which is carried by the magnifying spring, and voltmeters containing as many as twelve short wires, each about seven inches long, were made in the early part of the summer of 1886.

These instruments showed, however, the sluggishness which is familiar to the users of the Carlew voltmeter, and we had to set ourselves to investigate it. Stationary metallic screens were inserted between the wires to assist the cooling, and various other means tried, with out success, when we set Mr. Bourne to investigate the general question of sluggishness. A variety of experiments were made by him on the rate of variation of the permanent state of a wire with the variation of potential difference at its terminals, as affected by varying the proximity of the wires, their length, &c. This occupied him several weeks, and the experiments he made were too numerous to be recorded here. With our many-wire voltmeter the sluggishness was certainly not due to mechanical friction, as our magnifying spring is practically frictionless, and we gradually saw that the peculiar creeping back in the deflection of a Carlew voltmeter, when a perfectly constant potential difference was first set up between the terminals, was due to the fact that the draught of air created in the tube by the heated wires takes an appreciable time to be produced, so that the wires are hotter directly the potential difference is applied than they become when the draught begins to flow. A number of more or less successful devices were tried for overcoming this defect—for instance, even the employment of a draught independently maintained—when we found in the summer of last year that the simple device of placing the tube horizontal instead of vertical, and using very fine wire—not much exceeding one-thousandth of an inch in thickness—overcame all the difficulty. The importance of placing the tube horizontal was also sub-

* "A New Form of Spring for Electric and other Measuring Instruments."

† "Measuring Instruments used in Electric Lighting and Transmission of Power."

‡ "Thermal Effects of Electric Currents."

quently seen by Mr. G. S. Ram this year, and consequently the scales of the Cardew voltmeters are now marked so that the zero is at the top when the tube is placed horizontal.

This home-made instrument with two wires lying on the table was then completed in August of last year, and was found to be remarkably sharp and decisive in its action—to give a deflection of 300 with 14.22 volts maintained at its terminals. Even a fraction of a volt can be measured with it, as the readings are quite definite even near the zero.

The finest wire employed by Captain Cardew in his commercial instrument has a diameter of 0.0025 of an inch; but, in consequence of our magnifying gearing being frictionless and comparatively massless, we are able to use much finer wire—not more than 0.0014 of an inch in diameter—without any fear of injury, even if the instrument receive a sharp knock. This greater fineness of the wire gives us three times as much resistance per foot, and therefore enables the instrument to be very much smaller; also, as the ratio of surface to sectional area is far greater, the heating and cooling is far more rapid—that is, the instrument is much more dead beat.

Figs. 3 and 4 show two sections at right angles to one another

through the centre of this other two-wire voltmeter which is lying on the table. It has been constructed on the lines of the original one but in a more workmanlike manner. It is direct reading, and measures from 0 to 10 volts, the deflection for that potential difference being some 250. The same letters are employed to designate the various parts of the instrument as were used in Figs. 1 and 2, with the addition of *T*, the metal tube surrounding the wires, and the stirrup connecting the end of the magnifying spring with the wires is also shown.

The employment of several short parallel wires soon suggested the addition of the commutator described in our paper read before this Society in 1881, for varying the sensibility of a voltmeter. But whereas with our commutator ammeters and voltmeters in which the magnetic action of a current in deflecting a magnetized needle was employed the current had to flow through every wire in the same direction, whether the wires were joined in series or in parallel, with this new form of voltmeter

in which the heating property is employed it is immaterial which way the current passes through a wire. Hence the pins in the barrel of our old commutator which gave trouble may be entirely dispensed with, and the commutator assumes a very simple form. In fact, if *A, B, C, D, E, F, G*, (Fig. 5), represent wires joined in series in the new form of voltmeter, the series connections need not be disturbed when a parallel arrangement is required, since all that need be done to join them in parallel is to connect the points *A, C, E, G*, by means of the bar *L*, and *B, D, F*, by means of the bar *M*. *S* and *SP* are the terminals for series, and *P* and *SP* for parallel; so that if

the commutator be accidentally turned from series to parallel the circuit is broken and the wires are not fused. This instrument lying on the table is a four-wire voltmeter, and the sensibility is such that 15.2 volts gives a deflection of 58 when the commutator is turned to series, and 295 when it is turned to parallel.

It is important to notice that the employment of this commutating device to vary the sensibility enables all the wire in the instrument to be always operating in deflecting the pointer; whereas if the ordinary device of adding an outside resistance coil be employed to enable the voltmeter to measure a larger number of volts, the energy spent in heating this outside resistance coil is entirely wasted as far as deflecting the pointer is concerned. In fact, the greater the outside resistance, the more inefficient becomes the voltmeter.

For the object of still more completely carrying out the principle of employing a number of short wires, we have also made voltmeters in the following way. The wires are arranged like the spokes of a small bicycle wheel *W, W'* (Fig. 6); that is, we

have a circular rim of a wheel *R*, which may be of the same metal of which the wires are made, to eliminate errors due to change of temperature, fitted with non-conducting studs *A, B, C, D*, &c., to which the wires are attached. There is also a small non-conducting central piece *H*, corresponding with the hub of a wheel, to which the wires are also attached; and as the wires come from rim to middle backwards and forwards several times, the arrangement appears like a bicycle wheel with many spokes, as seen in Fig. 7. One end of a right and left-handed

magnifying spring *M* (Fig. 6) under tension is rigidly attached to the hub *H*, and its other end to the support *S*. Hence, as the wires expand on heating, the spring draws the hub *H* more out of the plane of the rim *R*, and the rotation of the pointer *P* measures the current. This instrument on the table is made exactly in this way. Using two of its three terminals, the range is from 0 to 50 volts, or using one of the previous ones and the third, it is from 0 to 100 volts. In both cases, however, the whole of the wire is operative in deflecting the pointer.

Fig. 8 shows a voltmeter made with two bicycle wheels. The letters attached to one of them refer to the same parts as the letters used in Fig. 6, while similar accented letters are used for the similar parts of the second bicycle wheel. As before, one end of the right and left-handed magnifying spring is attached to the hub of one of the wheels, but instead of the other end being rigidly attached to the case of the instrument it is attached to the hub of the other wheel. Hence the rotation of the pointer is produced by the expansion of all the wires on both wheels. Fig. 9 shows the actual arrangement of the double bicycle-wheel

voltmeter on the table, where an ordinary (not a right and left-handed) magnifying spring M is employed, with a flexible connection of fine wire carried by the support S , which itself is carried by the hub H of one of the wheels. The wires are

electrically divided into four sets. When the commutator is turned to series, 80 volts produce a deflection of 300; whereas

Fig 9

20 volts produce a deflection of 300° when the commutator is turned to parallel.

In Fig. 6 of the single bicycle wheel voltmeter the instrument is shown with the dial vertical. But any one of the forms described in this paper may also be used with the dial either horizontal or vertical.

The action of these instruments is quite easy to understand, but the mathematical calculation of the way in which the deflection of the pointer for a given potential difference is varied by varying the dimensions of the magnifying spring, the initial sag given to the wire, and the dimensions of the wire, is not quite so easy to work out. We have, however, succeeded in reducing the solution to a comparatively simple form, and the following comprises the consideration of—

- The general formulae and the law of graduation.
- Waste of power in the voltmeter.
- The range in volts of the voltmeter.
- The greatest angular deflection of the pointer.
- Uniformity of three scale divisions.
- Correction for temperature.

A.—GENERAL FORMULAE AND LAW OF GRADUATION.

Let $A O B$ (Fig. 10) be one of our fine wires or two opposite

spokes of our bicycle wheel form of voltmeter, the size of the hub being neglected. Let

$$A O = O B = \frac{1}{2} l,$$

$$O Q = r,$$

Let the diameter of the wire be d , and the specific resistance of its material be ρ when its temperature is θ degrees above the temperature of the surrounding metal case; then, if the case does not alter greatly in temperature,

$$\rho = \rho_0 (1 + k \theta) \quad (1)$$

where k is the coefficient of increase of resistance per degree centigrade, and ρ_0 is the specific resistance of the material when θ is nought.

When $\theta = 0$,
let $l = l_0$,
and $r = r_0$,
then $l = l_0 (1 + k \theta)$,

where α is the coefficient of increase of length per degree centigrade

$$l^2 + A Q^2 = \frac{1}{2} l_0^2,$$

$$l^2 + A Q^2 = \frac{1}{2} l_0^2,$$

since α is small. $\therefore l = l_0 - \frac{1}{2} l_0^2 \alpha \theta$, approximately ... (2)

In that very useful treatise of Dr. Everett's, "Units and Physical Constants," there are given the results of Mr. McFarlane's and of Professor Tait's experiments on the rate of loss of heat in air at ordinary pressure from copper for various differences of temperature between the copper and the surrounding space, but no indication is given as to the form of the radiating body, nor of its size, and hence people have used Mr. McFarlane's results as if they applied to bodies of any shape and size, and so have been led in some cases to erroneous conclusions. As a matter of fact, Mr. McFarlane's values for the rate of loss of heat by radiation and convection given in Dr. Everett's "Units and Physical Constants" apply only to a copper ball of 2 centimetres radius, since this, we find, was the cooling body employed by Mr. McFarlane in the experiments in question, as mentioned in Mr. McFarlane's paper communicated by Sir W. Thomson to the Royal Society in 1870.

But in a very valuable book published two years previously to that—viz., in 1868—by Mr. Box, and called a "Practical Treatise on Heat," there is given a table on page 151 (which has been much used by engineers) showing the loss of heat from contact with air with horizontal cylinders and spheres. It was deduced, we rather think, from M. Peclet's experiments, and it shows clearly that the loss of heat per unit area increases as the diameter of the cylinder or sphere diminishes. Mr. Box used the Fahrenheit scale for temperature, a square foot as his unit of area, a pound for his unit of mass, and an hour for his unit of time; but, reducing his formulae to the C. G. S. system, we find that the loss of heat (gramme, C.) per second, per square centimetre of surface, per 1° C. excess, is

$$0.00005710 + \frac{0.0001057}{a} \text{ for a long horizontal cylinder,}$$

$$\text{and } 0.00004928 + \frac{0.0003509}{a} \text{ for a sphere,}$$

a being in the former the radius of the cylinder in centimetres, and in the latter the radius of the sphere.

Applying Box's formula for a sphere to the case where a is 2 centimetres, the radius of Mr. McFarlane's ball, we obtain for the loss of heat (gramme, C.) per second, per square centimetre of surface, per 1° C. excess, the number 0.0002297—a number which is between Mr. McFarlane's value for polished copper (0.000178) and for blackened copper (0.000252). There is, therefore, every reason for believing that Box's formula is at any rate approximately correct.

Let us take as a first approximation that the rate of loss of heat is directly proportional to the difference of temperature.

This we know is not strictly true, and the error arising from the assumption will be further considered under section B. "Waste of Power in the Voltmeter." Then, if h be the heat-power in watts given out per square centimetre of surface of the wire when the excess of temperature is θ ° C.,

$$h = \frac{0.00005710 + \frac{0.0001057}{a}}{0.239}$$

Now the resistance of the wire is $\frac{4 l_0 \rho}{\pi d^2}$; so that if V volts be

the potential difference at its terminals, $\frac{V^2 \pi d^3}{4 l_0 \rho}$ watts are developed in the wire, and $l \pi d e \theta =$ heat-power emitted in watts, so that

$$l \pi d e \theta = \frac{V^2 \pi d^3}{4 l_0 \rho} \quad \dots \dots \dots (3)$$

$$\theta = \frac{V^2 d^2}{4 l_0 e \rho} \quad \dots \dots \dots (4)$$

If the thickness of the wire be very small, and if Box's formula continue to hold for very thin cylinders,

$$e = \frac{0.0001057}{0.299 d}, \text{ approximately;}$$

$$= \frac{0.0008848}{d}, \quad "$$

hence
$$\theta = \frac{V^2 d^2}{0.003539 l_0^2 \rho}, \quad "$$

so that to raise a fine wire of a given length, made of a given material, to a given temperature above that of the case of the instrument requires that the potential difference maintained at the ends of the wire shall be inversely proportional to the diameter of the wire, approximately.

If C be the current in amperes flowing through the wire,

$$C = \pi d i \sqrt{\frac{e \theta}{l \rho}}$$

Substituting the value just obtained for e for very fine wires, we have

$$C = 0.61487 \pi d \sqrt{\frac{\theta}{l \rho}}, \text{ approximately;}$$

so the current required to maintain a fine wire of a given material at a definite excess of temperature is approximately directly proportional simply to the thickness of the wire.

(To be Continued).

claims. A member of the board offered at his own cost to put himself in communication with his friends in Paris. He went over bringing the scheme to the notice of his friends. When there he made an arrangement with Count Dillon, and after this he went over at the request of the board to Portugal, and saw his Excellency Senhor Aguiar, late Minister of Public Works, and obtained an important extension of the contract for the concession from twenty to forty years. There were minor concessions, and I may say you cannot too much thank him, though he requests his name may not be mentioned. It will also be in the recollection of some of you that the British Government invited tenders for a cable from Halifax to the Bermudas. As this was part of our scheme and would have been a key to our cable, to which we felt we might look we entered into negotiations on the subject, and we have every reason to believe that if the British Government had not subsequently determined to defer the tender it would have been given to this company. Had it been so we should have been in a position to lay down our cable. However, the thing is not entirely dropped. An official from the General Post Office called last week on Mr. Sydney Thompson to know if the scheme was going on. If we had succeeded in this, we could have gone on and found funds sufficient for carrying out your entire scheme. Well, we have also had communications from America and Spain to work with the company, but until the main question is settled we feel it would be needlessly taking up time to consider these questions. At the present moment, the increased cost of copper is unfavourable, and that is one reason why we must consider, but on the other hand, there seems to be less desire on the part of the existing companies to continue the war of rates. Well, you must decide as shareholders what to do. Our position as directors has been anomalous. We always desired to go on if we could, and fairly and honourably. If the shareholders wish us to continue in office, I think we shall be willing to remain for six months. If on the other hand you come to the conclusion to close operations, we shall be prepared to resign and give the seven days' legal notice for meeting. We have the money subscribed lying at the bank at seven days' call, where it has been since we received it—excepting something less than £600 which have been required for expense of office, secretary, &c. The board made no charge, and as we have nothing more to add, I shall now be happy to hear your views.

After a somewhat warm discussion, during which the motion was made to wind up the company, and an amendment not to wind up the company, the amendment was carried, and, therefore, for the present, the company is not to be wound up.

A vote of thanks to the chairman concluded the meeting.

CITY NOTES.

Direct Spanish Telegraph Company. The estimated traffic receipts of the Direct Spanish Telegraph Company for December were £2,001, against £1,782 for the corresponding period of last year.

Empire Telephone Company. The customary notice has been given by the Liquidator of a general meeting of this company on the 28th January 1888 at 60, Queen Victoria Street, for the purpose of having the Liquidator's accounts.

Brazilian Submarine Telegraph Company. The traffic receipts of the Brazilian Submarine Telegraph Company for the past week amounted to £4,192 and those of the Western and Brazilian Company, after deducting the fifth of the gross receipts payable to the London Marine Brazilian, were £3,318.

Eastern Telegraph Company. The traffic receipts of the Eastern Telegraph Company for December amounted to £57,703, against £52,825. Those of the Eastern Extension, Australasia, and China Company for December amounted to £58,903, against £40,539 for the corresponding period of 1886.

Great Northern Telegraph Company.—The traffic receipts of the Great Northern Telegraph Company for December were £21,600, making a total from January 1 to December 31 of £261,480, against £258,660 and £284,720 for the corresponding months of 1886 and 1885 respectively.

West India and Panama Telegraph Company.—The estimated traffic receipts of the West India and Panama Telegraph Company for the half month ended December 31 were £2,826, against £3,089 for the corresponding period of 1886. The September receipts, estimated at £4,357, realised £4,453.

Carbon Trade. We are requested to state that after January 1 the Globe Electrical and Engineering Company of 7, Carteret Street, Westminster, will act as London agents for the Battey Carbon Company of Battey and will supply both carbon rods and plates from their London stores at the same price and terms as the Battey Carbon Company.

West Coast of America Telegraph Company.—The traffic receipts of the West Coast of America Telegraph Company for December were £4,300. The number of messages passing over the lines of the Costa Submarine Telegraph Company during December was 3,625, estimated to produce £1,500, against 3,625 messages, producing £1,500, in the corresponding month of last year. The traffic receipts for September, estimated at £2,309, realised £2,494.

COMPANIES' MEETINGS.

THE INTERNATIONAL CABLE COMPANY.

The annual general meeting of the International Cable Company Limited was held at the offices, 34, Nicholas Lane, E.C., on Thursday, December 29, W. J. Thompson, Esq., in the chair. There were also present Baron Da Costa Ribeiro, Mr. Da Roca, Mr. J. W. A. Jensen, Messrs. Giddon, Pope, Holroyd, Soren, Dain, Quirk, Captain Wood, Mr. Sydney Thompson, Mr. Fox, Mr. Macpherson, Mr. Bartlett, and others.

The Chairman said, I appear before you as the chairman of a company which had a very warm reception at its start. Now, we were quite prepared for opposition, as the many supporters of the existing companies were sure not to be friendly to our scheme, and certain parties thought themselves justified in casting ridicule upon it in the Press; but having been engaged in this project now myself some considerable time I must acknowledge the courtesy which I have experienced from all concerned in it, and through some people have made strong remarks they never cast any reflection on the directors, and I may even go further and say that had they looked through other commercial classes their verdict would have been with us. There is only one matter that I would further mention on this subject, and that is that some reference should be made to a remarkable letter which I think damaged this Company most seriously and even at this time I cannot realise what the writer might have intended, or whether he really weighed in his mind what would be the effect of his words. The letter damaged this scheme, but you will hardly credit it that the writer was at that time a director, if not the chairman, of a syndicate who were anxious to promote this scheme. We shall now ask your opinion as to what you wish us to do in this matter in future. We have then joined that the proprietor of a single share in the company was much entitled to live in comfort as the holder of 100. Had we shared our own case and comfort we should have retired as soon as we found the profits built back. We had large promises from Liverpool and Glasgow which failed; but as there were large subscriptions from parties professionally anxious to see the scheme carried through the line was laid they should not resign as long as there is any appearance of success. They determined, however, that, unless they could be satisfied that there were sufficient funds to carry out the scheme in its integrity, they would not risk the money of the subscribers, although there were frequent requests to commence. Certain foreign subscriptions proving doubtful was another reason for over caution. Your directors have worked at their own personal cost, and hoped to the last and on hope has not been abandoned. The promoters, on their part, met the different position most frankly, and consented to forego half their

THE ELECTRICAL ENGINEER

No. 2, Vol. 1.—New Series.

LONDON, JAN, 13, 1888.

Price 3d.

NOTES.

Garston. The sugar refinery and docks of Messrs. Batcock and Co., Garston, are to be lighted by electricity. The Lever system is the one to be adopted.

Objection to Electric Light.—The Parisian actors complain that the substitution of electric light for gas in the theatre renders the stage so cold that they suffer.

The Grand Theatre.—Steps are already being taken for the recreation of the ill-fated Grand Theatre, and it is anticipated that a new building, lighted entirely by electricity, will be finished by Easter.

Provisional Order. Notice has been given, in accordance with the Electric Light Act of 1882, by the Liverpool Electric Supply Company for a Provisional Order. It is understood that the company intend to light a considerable part of Liverpool.

Photo-Electric Currents. Dr. Moser finds that the electromotive force produced by the action of sunlight on chloride, iodide or bromide of silver plates, can be considerably increased by immersing them in a bath of erythrosin or some similar dye.

The Gramophone.—An improved apparatus under this name apparently a combination of Edison's *phonograph*, Graham Bell's *graphophone*, the *phonantograph* of Leon Scott, and the perfected *phonantograph* of Charles Gros—has been constructed by Mr. Berliner, of New York.

Bradford.—It is said that the plans and specifications relating to the proposed electric lighting experiments in this town are to be submitted to Dr. J. Hopkinson, in order that he may give his opinion concerning them, and for this purpose an early visit to Bradford will be made.

Electric Light and Books.—Attempts are being made to prove that the electric light is more injurious in a library than gas. Of course, this is not so; the effects of gas are ruinous to all good binding, the effects of the electric light are confined to the deepening the colour of paper made of wood fibre—otherwise it is harmless.

Fog and Smoke.—Three or four days of a London fog make one desirous of seeing Dr. Lodge's suggestion practically tested on a large scale. By the way, ought not the multitudinous overhead wires to have some remedial effect, or are the currents conveyed telephonically or telegraphically of such a character as not to produce any effect?

Electric Lighting in India. Lord Dufferin's new Viceroyal lodge at Simla is to be lighted throughout by electricity; nearly 1,000 glow lamps will be employed. The circumstance is noteworthy, inasmuch as this is the first Indian palace so lighted. The work is to be carried out

by Mr. W. H. Massey, of Twyford, Berks, electrical engineer to Her Majesty.

Electric Lighting in Parliament. It is estimated that to light the whole of the buildings connected with the House of Lords and the House of Commons, 5,000 lights will be necessary. At present only 500 electric lights are used, and these have given such general satisfaction that the impression exists that the necessary extension will be readily sanctioned.

The British Association. Already steps are being taken at Bath to insure ample and comfortable quarters for the British Association, which meets in this town in September next. It is proposed to erect a temporary building adjoining the Assembly Rooms, to serve as a reception room. This building would be 150 or 160 feet long and 35 feet wide.

Cardiff.—The first of the bachelors' balls at Cardiff was given at the Cardiff Town-hall last week. The Assembly Rooms were tastefully decorated by Messrs. Trapnell and Gane, and variegated lamps, illuminated by the electric light, furnished by the Anglo-American Brush Electric Light Corporation, encircled the room, adding greatly to the effective decorations.

School of Electrical Engineering.—We have received an illustrated pamphlet which may be said to be a prospectus of this school. It describes the work of the school, and gives the press and other notices which have been obtained. The school has now been in existence twenty years, and should therefore be well known to the members of the profession.

Book Received. *Formulaire Pratique de Electricien*, by M. E. Hospitalier. This well known book has been corrected to date, and is undoubtedly filled with exceedingly useful information for all electrical engineers. We find, for example, that it contains mention of the new Kapp machine specially designed for use with transformers, giving a tension of 2,000 volts.

The Electric Light for Bournemouth.—The scheme laid before the Bournemouth Commissioners, by Mr. Andrews, the Town Surveyor, for the illumination of the gardens, the pier, and a portion of the town, by utilising the spare energy at the refuse destructor, has received strong support at the hands of Mr. W. Lynd, M. S. Tel. E. and E., who has written on the subject at considerable length in the Bournemouth paper.

Bute Docks, Cardiff.—Further information as to the lighting of these docks is to hand, and we find that the lights are being installed by Messrs. Crompton & Co.—not the Brush Co. as was originally reported. The scheme of lighting has been prepared by Sir W. Lewis and Mr. Hunter, the engineer to the docks, and a part only as yet of the

scheme is being carried out, as we say, by Messrs. Crompton & Co., under the supervision of Mr. W. H. Massey.

Cheltenham. The Corporation have under discussion the question of introducing the electric light for illuminating a portion of the town. The members of the Corporation seem unanimous in their desire to introduce the light, but no decision has yet been come to, the immediate trouble being to decide if the subject shall be decided by the Streets and Highways Committee or by a special committee of the whole Council, with power to call in skilled assistance.

Testimony to Reckenzann. Mr. Wharton, President of the Electric Car Company, says that one of their new eight wheel cars, with Reckenzann motors and an Electric Accumulator Company's battery of 116 cells, ran a distance of 63 miles 211 feet in eight hours, with one charging of the battery. In the run there were 331 curves of 33ft. radius, 662 of 50ft., and 331 curves of 100ft. radius, besides 5 miles 2,390ft. of 5.8 per cent. ascending grades.

Germany. Electric illumination has recently made great strides in Germany. According to a statement by Dr. von Stephan, the German Postmaster General, it may be assumed that at the present time there are at least 15,000 arc lamps and 170,000 glow lamps in operation, which receive their light from 4,000 dynamos. If we reckon nine glow lamps and one and a half arc lamps for each horse-power, there are now over 30,000 horse-power employed in producing the electric light.

The Swansea Telegraphists. The annual dinner of the Swansea Telegraph staff was held at the Albany Hotel a few nights since, every available member of the staff being present. The evening's proceedings were presided over by the superintendent (Mr. Edwards), and the utmost enthusiasm prevailed throughout. The usual toasts were proposed and responded to by Messrs. Edwards (superintendent), Desmond, Christy, Johns, and Critchley, and subsequently an entertaining programme of vocal and instrumental music was rendered by various other gentlemen.

American Institute of Electrical Engineers.—The American Institute of Electrical Engineers has begun, in its monthly issue of *Transactions*, an index of current electrical literature, dating from October. The permanent value of such an index to electricians and the scientific public is apparent. The present instalment contains references to more than 300 distinct articles, cited from 18 papers and periodicals which are regularly indexed each issue, and from about 50 journals in all. Subsequent issues will comprise the leading electrical publications in foreign languages.

Indian Colliery Lighting. The electric light has been introduced into the East Indian Railway collieries, at Giridih, by the manager, Mr. Walter Saise, M. Inst. C.E., F.G.S., and marks the opening of a new era in Indian mining. The machine used is a 30-lamp dynamo, worked by a 2½ horse power vertical engine, which is supplied by steam from the pit-winding engine boilers, so that the cost of working is practically nil. The lamps used are the ordinary incandescent. The miners are said to be delighted with the innovation, and go to their work with greater confidence than before.

Telephones for Buenos Ayres. A company in Buenos Ayres has recently ordered the material for a complete system of telephones from the Societe Generale de Telephones at Paris. *Annales Industriels* states that

over two thousand subscribers have been obtained, and the company proposes to erect a tower in the river, which will serve as a maritime telephone station. The harbour of Buenos Ayres is shallow, so that vessels are obliged to anchor several miles from the city. Telephone communication by means of a tower near the anchorage will be serviceable.

Temporary Lighting.—The occasion of the annual ball given to the staff of Thorpe Asylum, near Norwich, on the 6th inst., was this year made especially agreeable by the lighting of the hall by means of incandescent lamps, giving 4,200 c.p. The motor driving one of Messrs. Paris and Scott's C-type No. 2 dynamos was a rotary engine brought out by Messrs. Sturges and Towellson, of Norwich. Motor and dynamo were coupled together and bolted to a cast iron bed plate 3ft. by 2ft., and running at 1,300 revolutions per minute. It was especially remarked how steady the light was, and how cool the hall remained even at the early hour of three in the morning.

Russian Train Lighting. The plant used upon the trains lighted by electricity consist of a Crompton compound dynamo machine. At present the lighting takes place only on certain express trains, and in tunnels between Kieff and Odessa. There are three circuits of 2,000, 1,460, and 6,540 feet respectively. The rails are used for the return conductor, and the other wires are laid in a central tunnel between the tracks. Contact is made in each tunnel with the wire for that circuit by contact pulleys on the car axles. Each car has its own contact with the wire, so that all complicated connections of coupling a train are avoided. The train may stop while in the tunnel and the system will continue to operate. The company has applied the system to seventy four cars, and they report that the expense of the system is less than one-third the cost of gas.

Theatre Lighting. In another column we treat this subject at some length in an abstract of a paper by Dr. G. Sous, but we may here point out that the paragraph industriously circulated by the gas interest is misleading. A contemporary says:—"On the occasion of the opening of Mr. Terry's new theatre in the Strand, we mentioned that the electric light had been fitted up in conjunction with gas all over the house. At the present time, in addition to this theatre, only the Criterion, the Savoy, and the Prince of Wales's, are lighted by electricity, so far as the stage is concerned. At the Haymarket the electric light is employed in the auditorium." The hasty reader would probably take this to mean that at the Savoy, &c., the electric light was not installed all through the house, but only partly, and that on the stage. Of course it is not so. For the above read "the electric light is used throughout the house as well as on the stage."

Walker's Portable Miners' Electric Lamp.—Mr. Sydney F. Walker is introducing an electric lamp worked by a bichromate battery. It is made in two forms, a round one, in which are two cells of a bichromate-carbon-zinc battery, and an oval one, which has three. The cells are made in a particular form, the carbon itself being the containing vessel. On one side is a strong lens, faced by a parabolic reflector, the two being held by a strong brass cylinder attached to the outer case, which is also of brass or copper. The cells contain the usual porous cells and zincs, and are closed by an india-rubber pad, above which the connections are made in a simple and efficient manner. A second pad of india-rubber is placed above this, and is

retained in its place by the cover, which is held by screws or a lock, as desired. A stout handle by which to carry the lamp surmounts the whole. The smaller lamp weighs 5 lbs., and is said to give, for 10 hours, a light sufficient to read ordinary newspaper print at 6 ft. from the lamp. The cost of renewing the chemicals used, the incandescent lamp, and incidental repairs, is stated to be not more than $\frac{1}{4}$ d. per day for the small lamp and 1d. per day for the large one.

Electric Railways in America.—Electric traction is a recognised institution in America, and is rapidly extending. The Van De Pöle system is in use at Windsor, Ont., where two miles of line are in work with two cars, costing four dollars per day for sixteen hours. The steam power is rented. At Detroit, Michigan, there are also 2 miles of line, but these are only worked for 8 hours per day, at a cost of six dollars. Steam power here too is rented. At Appleton, Wis., water power is used. Here there are 5 miles of line and 5 cars, costing per day \$4.50. At Port Huron, Michigan, 5 miles of line with 5 cars cost \$3.70 only, the motor power being natural gas; Scranton, Pa., has $4\frac{1}{2}$ miles, with 7 cars, costing \$7, coal dust being used; Binghamton, N. Y., has $5\frac{1}{2}$ miles and 6 cars, costing \$10, with rented steam; Lima, Ohio, has 4 miles and 6 cars, costing \$4, crude oil being used; St. Catherine's, Ontario, has 6 miles and 6 cars, costing \$4 with water power; Montgomery, Alabama, has 13 miles and 18 cars, costing \$14 with water power; Jamaica, L. I., has 6 miles and 10 cars. The total line worked on this system is thus 53 miles on which 73 cars are running, while 16 $\frac{1}{2}$ miles of line to carry 26 cars are under construction, viz., Ansonia, Conn., $3\frac{1}{2}$ miles and 4 cars; Omaha, Neb., 7 miles and 10 cars, and Dayton, O., 6 miles and 12 cars.

Atlantic Cables. On Monday the Tribunal of Commerce gave judgment in the action between the Poyser Quartier Company and the Anglo-American Telegraph Company, ordering the former to carry out the conditions of its agreement with the Anglo-American Company. It will thus be understood that the Anglo-American Telegraph Company, and the other companies affiliated with it, have won a decisive victory over the French Atlantic Cable Company. Originally the French company was started in antagonism to the English companies, but subsequently joined the "pool," breaking its agreement when the English companies seemed hard pressed by other competitors. The Anglo company instituted proceedings in the French Courts against the Compagnie Française, and the case was tried before the Tribunal of Commerce, the Compagnie Française being condemned on all points. They were ordered to pay damages amounting to 2,000 francs per day since they broke out of the "pool," and were further ordered to resume at once their contract with the cable companies. This means that, besides paying a very large sum to the "pool" companies, the French company will be compelled to withdraw from the Mackay Bennett combination, and the "pool" companies thus regain a card which will assist them to force their adversaries' hands. However, the position of the Anglo-American Company is strengthened more because of its £1,000,000 reserve than because of any "pool" combination.

Lectures by Mrs. Ayrton.—A course of elementary lectures on electricity is announced to be given by Mrs. Ayrton, at 2, Upper Phillimore Gardens, on Jan. 17, and the five following Tuesdays. Mrs. Ayrton is a Graduate of Girton College. The syllabus of the lectures is as follows:—Jan. 17—*What Electricity can do for us.* (1) In our House-

hold—Lighting, ringing bells, winding clocks, working machines, such as sewing, boot-cleaning and plate cleaning machines, telephony. (2) Out of Doors—Lighting large spaces, fire alarms, driving tricycles, cabs, tramcars, trains, launches, transporting goods. (3) In our Manufactories—Electro plating, electro typing, purifying metals. Jan. 24—*The Different Ways of Obtaining a Supply of Electricity.* Electricity among the Greeks. Galvani and Volta's discovery of the Electric Current. Galvanic Batteries. Energy its different forms. The Conservation of Energy. The purposes for which Galvanic Batteries are economical—bells, signals. Jan. 31—*Faraday's Discovery. How to Produce Large Currents.* Electric pressure or potential. The difference between a good Conductor such as copper, and an Insulator such as gutta serena. Importance of good insulation to prevent accidents and waste. Lighting of the Grosvenor Gallery, St. James's Hall, &c., by the Grosvenor Gallery Electric Supply Association. The distance through which large currents can be sent. Deprez's Installation 37 miles. The storage of Electric Energy. Feb. 7—*Electric Lighting for Houses.* Incandescent Lamps how they are made. The cost of lighting (1) a dinner table, (2) a ball room, (3) a house with incandescent lamps for one evening. The cost of lighting a house permanently with incandescent lamps. The Electric Lighting Act—How it has impeded the use of Electricity in England. Feb. 14—*The Physiological Effects of Electricity.* Galvani's Experiment with the Frog. Need for scientific precision in the application of Electricity to the cure of Disease. An Electric Hospital. Why lightning is dangerous. Why Trees should be avoided in a thunder-storm. Lightning Conductors—worse than useless unless properly constructed. Points to observe when they are put up. Feb. 21—*Transmitting Messages, Music and Song by means of Electricity.* The Telegraph. Submarine Cables. The Telephone. The Microphone or Sound Magnifier. The Phonograph. Seeing by Electricity—can it be accomplished? The Future of Electricity.

Italian Military Preparations.—Captive balloons for the Italian army in Abyssinia have been made in Paris under the supervision of Count Pecori Gerardi, director of the Italian aeronautic service. They are lighter than those hitherto used for purposes of military reconnaissance, being only 331 cubic metres in volume instead of 500, and having a diameter of eight metres. This reduction of size renders it unnecessary to have a steam engine to work the windlass on which the rope holding the balloon captive is wound. Six hundred men are sufficient for the purpose, and in case of need even the windlass may be dispensed with. [The correspondent of the *Globe*, who is answerable for this, does not say how six hundred men are going to work on the windlass.] Count Pecori Gerardi has also obtained a balloon in England, which with a volume of 180 cubic metres can raise an observer 500 metres high. It is made of goldbeater's skin of great strength, the net and rope being of silk, and the car weighing only two to three kilogrammes. The use of the telephone to speak from the car to the ground, or even to the quarters of the commanding officer, by reducing the number of observers, has tended to diminish the size and weight of captive military balloons. Count Pecori Gerardi has, in addition, adopted a small balloon of 50 cubic metres for signalling at night, by means of electric incandescent lamps, placed outside the balloon and in front of a reflector. This mode of fixing the lamps has been preferred, because the shell of the balloon, though translucent, is not very clear, and would cut off a great part of the light were the lamps enclosed within it, as is sometimes

done. A Morse key to 'make' and 'break' the current is part of the outfit: so is an aspirator to transfer the gas from one balloon to another. The gas is made at Naples and sent to Massowah in light steel tubes, each containing 4,000 litres in a volume of 32 cubic metres, and at a pressure of 125 atmospheres, the tubes being capable of withstanding a pressure of 220 atmospheres. These tubes will be carried on camels in the desert tracts and on mules among the mountains. The weight of the tubes necessary to supply the gas by chemical means on the spot. It is expected that the balloons will not only be useful in Abyssinia for purposes of strategy, but also in disconcerting the enemy." Is not the signalling arrangement here described due to Eric A. Bruce?

Electrolysis in Sanitary Matters.—According to the article in the *Standard*, "electricity, which has served so many purposes in science and in the Arts, now promises to rescue civilisation from one of the most pressing difficulties which beset it. The Metropolitan Board are about to expend a sum of nearly, or quite, a million sterling in purifying the London sewage, so that the Thames shall be delivered from its present state of pollution. The process to be employed is of a chemical nature, and enormous works for the purpose of carrying out the project are in course of construction at Barking, to be followed by others of a similar nature at Crossness. At this juncture a plan of an entirely novel character is being perfected, which has the appearance of dealing successfully not only with the whole sewage problem, but also to a large extent with the question of the water supply of town. The plan has been devised by Mr. Wm. Webster, F.C.S., son of the well-known contractor, who has had so large a share in executing the drainage works of the Metropolis. For certain reasons connected with the Patent Office, it would not be fair to the inventor to enter at present into all the details of his process, but certain results can be stated which will establish the importance of the undertaking. A current of electricity, produced either from cells or from a dynamo, is sent into the sewage, the transmission being effected through metallic electrodes. Instead of casting chemical ingredients into the sewage, the inventor adopts the plan of creating his chemicals in the sewage itself, by the action of the electric current on the electrodes and on the sewage. The effect is curious, and it is well seen when the liquid is exposed to view in a glass vessel. An inky fluid, obtained from the Deptford pumping station of the Metropolitan Board, has all its particles set in a circulatory motion by the electric current, a kind of procession taking place from the top downwards and from the bottom upwards. The sum total of the movements consists in landing the suspended particles at the top of the liquid, thus exactly reversing the usual chemical process, which sends everything down in the form of a precipitate. The upward action is due to the presence of certain gases, at first extricated by the electric current, and afterwards mingling with the organic matter so as to give buoyancy to the latter. By agitating the liquid, the gases can be sent off into the air, and the solid particles will then descend to form a precipitate, showing no tendency to permeate the fluid as before. But, as will be shown presently, there is no need to effect this precipitation. So prompt is the effect of the electric current, that in the space of twenty minutes a volume of opaque sewage becomes perfectly transparent, except at the top, where the organic matter collects in a semi-solid form." It will be seen from the above that if the effects produced are the same on a practical scale as they are in the laboratory, it is possible that the discovery may

lead to increased activity in the construction of dynamos and similar apparatus.

Station Lighting in America.—Among the papers contributed to the International Railroad Congress at Milan was one by Mr. G. W. Blodgett, Electrical Engineer of the Boston and Albany Railroad, from which the following data are taken relating to electric lighting by that company at East Boston: "Brush lamps of 2,000 nominal candle-power are used. In the buildings they are placed 14ft. high, which was the greatest height which the construction of the buildings permitted. Out of doors the height is 24ft. Although there are 48 lamps, only 36 can be operated at the same time, which is the full capacity of the dynamos. Electric light is used only when the number of lamps needed is nearly the capacity of one dynamo; that is to say, 18. The cost of the electric apparatus at East Boston, in place, was as follows: Buildings, \$3,116.12; 60 horse power engine, in place, \$1,737.10; shafting, pulleys, &c., in place, \$364.29; belting, \$412.30; two Brush No. 7 dynamos, \$1,000; 44 lamps, with two sets of carbons, \$3,520; two regulators for the dynamos, \$250; wires, insulators, telegraph poles and crossarms, and labour in setting up the machinery, lamps and wires, \$1,322.75; total, \$11,722.56. The cost of operation during the year ending Sept. 30, 1886, was \$2,277.34, or \$7.28 per day, or 20 cents per lamp per day, assuming 36 are used. The average daily use is about 10 hours for the whole year. At Boston the passenger-station, train-house and yard are lighted by 33 arc lamps and 12 incandescent lamps. There are two Brush dynamos of 16 lamps each, and as they are run at a speed of 825 in place of 750 turns per minute, 18 lamps can be used instead of 16. They are placed at a height of 12ft., except 5, which are about 24ft. high. The cost of the apparatus, not including the engine or boilers (which are in use by the repair shops) was as follows: Two Brush dynamos, \$1,000; 33 double arc lamps, \$2,640; 2 single arc lamps, \$120; 2 automatic regulators for the dynamos, \$250; wires, insulators, fixtures, &c., and work of setting up the apparatus, not including the main shafting, &c., \$1,206.47; total, \$8,216.47. The cost of operation for the year ending Sept. 30, 1886, was \$6,465.11, or \$184.72 per lamp per year, or 50.6 cents per lamp per day. The cost per lamp per hour under these conditions was about 6 cents. The cost of power furnished by the motive power department is \$2.50 per day, besides the wages of the engineer. Carbons cost about 80 cents per day; oil-waste, &c., about 3 cents per day. The cost of repairs to 5 Brush machines during the 6½ years of use has not been, it is estimated, more than \$150. Neither a lamp nor dynamo has yet been replaced nor sent to the factory for repairs. All such have been made by the men in charge of the apparatus. These installations were the first by a railroad company in New England, if not in America, and are still the most extensive. At Worcester the passenger station is well lighted by 20 arc lamps, placed about 15ft. high in waiting rooms, and 24ft. in the train house. The cost is about twice as much as formerly paid for gas (which was never satisfactory), but several times the amount of light is obtained. The cost is 70 cents per lamp per night. It costs about the same at Springfield. At Pittsfield the electric light company light the passenger-station for the same price formerly paid for gas—about \$1,400 per year."

The Vienna Opera Lighting.—The *Glasgow Herald's* correspondent, writing on this subject, says:—"It will be remembered that some weeks ago the Vienna Opera House

was closed by order, and remained shut for several days, owing to alleged defects in the arrangements for the electric lighting. This was no small event, and it excited passionate discussion, as the court officials, who have the imperial theatres under their management, sought to throw on the English contractors (the Imperial Continental Gas Association) the whole blame for what had happened. Those conversant with the facts were quite aware that the people really to blame were the incapable court officials, and this has now been brought out by the report of the scientific experts who have had to investigate the whole affair. The story offers so curious an illustration of the treatment which English companies have to suffer at the hands of Austrian bureaucracy that its details ought to be noted in England and Scotland, the more so as Austrian officials, when anxious to attract British capital for public works, are generally disposed to make all the preliminaries of negotiation so deceptively smooth that investors are lured on till they have passed the point at which withdrawal is convenient or possible. In the case of the British company which lights Vienna with gas, the acceptance of the contract for lighting the two Court theatres by electricity was a distinct favour which the company confessed no other company could or did offer such advantageous terms. The company has a large staff of employees and workmen, and an experienced staff of inspectors, and it possesses in Mr Herbert Lindon, its general manager, an administrator of first rate ability, with a thorough knowledge of Austrian ways. All this was recognised by the Court Intendancy, and as usual the first part of the business about the contract glided as on wheels. Once the contract had been signed, however, one thing after another began to be stipulated, so as to enable this and that official person to secure pickings at the expense of the contractors. Eventually Count Taaffe, the Austrian Prime Minister, himself insisted that the boilers at the Central Electrical Station should be of Austrian make. The English engineering contractors, Crompton & Co., of Chelmsford, had been about to order the boilers from a Glasgow firm (Babcock & Wilcox), but in deference to Count Taaffe the designs for the boilers were sent to the Austrian firm of Witkovitch, which is financed by the Rothschilds. The result was that six boilers were put in, which began to crack after two months. A Commission was summoned, reported the boilers to be dangerous, and ordered the closing of the opera. On this a furious outcry was raised against the English Company, the firm of Witkovitch declaring that the fault lay in the design of the boilers, not in the materials of which these were made. The whole matter was then referred to a commission of arbitration composed of Austrian experts, and these have now thrown the whole blame on the Witkovitch firm, which is proved to have manufactured the boilers in the most clumsy way with worthless iron. As a result the Witkovitch firm will have to pay all the expenses for closing the opera (3,000 florins a night for 10 nights), besides the cost of putting in new temporary boilers and buying a set of six new permanent boilers. These have been ordered from Babcock and Wilcox, of Glasgow. We have previously given the true facts of the case as regards the faulty boilers, yet it seems but just that the above information on what might well be termed the business proceedings, should be as widely known as possible.

Telephony over Long Cables.—Mr. T. D. Lockwood, in a note contributed to the discussion of Mr. Cuttress's paper before the American Institute of Electrical Engineers,

refers to the possible practicability of telephonic transmission over long submarine cables; and although his conclusions are those of every thoughtful electrician, they may be given for the sake of those whose knowledge of telephony is derived from experience in towns or on comparative short overhead lines. Mr. Lockwood says:—"You are all aware that in telegraphy it has been found possible to clear cables of charges by sending after each impulse of definite direction a clearing impulse of opposite direction, by which the static charge of the conductor was neutralised and the line cleared for the transmission of a second signal. The first idea regarding the transmission of telephonic or voice currents over submarine cables is in favour of its practicability, for it may be argued, since the foregoing practice aids the transmission of telephonic signals, and since telephonic currents, as usually transmitted, consist of a series of rapid alternations, why have we not here just the conditions of success. The truth is we have not, for in telephony the changes occurring are infinitely *too* rapid. They cannot serve the purpose of clearing the line; they rather serve the purpose of blocking the line, for the successive and consecutive impulses of opposing direction succeed one another so swiftly that they practically neutralise one another. Take, for example, the magneto telephone. It is well known that the currents generated by this instrument when used as a transmitter are alternating, and follow one another with extreme rapidity, so that for a long time it was thought that they were so infinitesimal as to be immeasurable. Suppose we have a fine galvanometer, and telephone through it. We see no deflection, but not because the current is so small, but because the plus currents succeed the minus currents of like potential and strength so fast that the needle cannot respond, and therefore does the next best thing and stays at zero. Let us now consider the battery transmitter and induction coil. A moment's consideration will show us that we have a close analogue to the operation of the magneto telephone. For though it is true that in the battery transmitter the action of the diaphragm merely varies the resistance of the circuit, and consequently the *strength of current correspondingly but in inverse* ratio, yet it is none the less true that the use of the induction coil develops currents in the secondary circuit and line which are alternating, because caused by the successive rise and fall of current in the primary circuit. Consequently these currents are subject for long circuits of high capacity to the same drawbacks as those of the magneto telephone. We have then at present only one other alternative method, namely, the plan of including the battery and transmitter in the main line, and allowing the transmitter to vary a permanent current flowing in the main line, thus dispensing altogether with the coil. But this also is impracticable, because the very small proportion of variation in the total resistance of such a circuit, cannot develop fluctuations of sufficient strength to satisfactorily influence a receiving instrument. I am therefore convinced that electric telephony—that is the transmission and reproduction of the human voice—will not, at least in the near future, be possible over long cables. Electro-static induction and the retardation and prolongation resulting therefrom is the reason. When I say *long* cables, I mean for example those over 100 miles long; and it would be difficult and not commercially successful over much shorter distances. My conviction is that those who advertise the operation of telephones over Atlantic cables, either do not know what they are talking about; or knowing, wilfully make misstatements for prospective personal gain."

CONTINUOUS CURRENT TRANSFORMERS.

The problem of translating high tension continuous currents into those of low tension is just now attracting considerable attention in Germany and Austria, and the two leading electrical papers in those countries, viz., the *Elektrotechnische Zeitschrift* and the *Zeitschrift für Elektro-technik*, have in their current numbers articles on this subject. Both these articles are examples of how not to do it, and illustrate in a striking manner the old proverb that a little knowledge is a dangerous thing, especially if such knowledge leads to theorising on a very scanty experimental base. The articles in themselves are therefore of very little practical value, and would hardly merit the attention of electrical engineers, but as the errors gravely expounded by our contemporaries, of one length, as if they were sound scientific truths, might lead some of our readers into costly and useless experiments, we propose to give in the following a brief abstract of these papers, and to point out where the fallacy lies.

FIG. 1.

The writer in the *Elektrotechnische Zeitschrift*, which, by the way, is the official organ of the Berlin Society of Electricians, expounds the principle of continuous current transformation as if it were a new discovery. The system he proposes is to wind a Gramme ring with two currents, each having its own commutator and pair of brushes, which are to be set at right angles to each other, so that when revolving the ring and keeping the brushes stationary, or revolving the brushes, the secondary coils should cut through the field produced by the primary coils. The idea that the field would necessarily be very weak and the self induction in the commutating coils of the primary winding enormous, does not seem to have occurred to this

FIG. 2.

writer; and the fact that he could in sober earnest propose so absurd an arrangement is internal evidence that he has never practically tried it. Had he done so he would have found his primary commutator within a short time transformed into a mass of fused metal.

The system of Messrs. Jehl and Rupp, elaborated at length in the journal of the Vienna Society of Electricians, is not much better, though the details are certainly ingenious. The author starts with the consideration of a compound wound Gramme ring (Fig. 1), but recognising that the flow of lines, represented by the dotted lines, must necessarily be weak, owing to the great resistance of the air space, he improves upon this design by inserting a second ring or cylinder as shown in Fig. 2. To still further reduce the magnetic resistance of the air gap, the secondary winding consists of iron bars, and great stress is laid on the fact that owing to ring and cylinder being stationary no clearance is required—a great improvement over the transformer with a revolving armature. The primary winding is of the Gramme type, and placed on the ring, whilst the secondary winding is of the drum type

and placed over the internal cylinder. To revolve the field a so-called distributing commutator (Fig. 3) is employed. It consists of a cylinder of insulating material into which are fitted metal strips of varying length. In our illustration the surface of the commutator is sup-

FIG. 3.

posed to be opened out to show all the strips. The wide brushes bring the main current, and each of the narrow brushes is in connection with one loop of the Gramme winding. When the commutator is revolved by an electro-motor the current is successively shifted from one brush to its neighbour, and the field created in the Gramme ring is

FIG. 4.

accordingly revolved. The secondary winding is similarly connected with another set of brushes placed at right angles to the primary set, but on the same commutator, an arrangement obviously possible because the metal strips are insulated from each other. In another arrangement, shown in Fig. 1, two commutators are employed, each con-

FIG. 5.

sisting of a number of metal rings insulated from each other, but severally connected with the segments of an ordinary commutator on which the main brushes rest. The motor revolving the commutator is shown at M, and is supposed to be worked from the primary circuit *ab*, and A B is the secondary circuit feeding the lamps. How this small

to be constructed for working under a pressure of 2,000 volts the inventors do not state. Next, however, an alternative design (Fig. 5) in the formation of the motor is performed by the field magnet B revolving by the attraction of the poles N S in the Gramme ring. The commutator in this case be fixed to the spindle of the field magnet, and designs the polar line of the secondary winding at angles to that of the primary winding, and, consequently, the commutation in the coils of the primary takes place in the strongest part of the primary field. It is needless to say that under these circumstances there will be excessive sparking at the brushes and the motor would probably be burnt up in a very short

time. It is difficult to see why these Continental electricians have devoted so much ingenuity on a system which is very complicated but radically defective. The very simple device originally invented by Gramme, copied by Messrs. Paris and Scott, of Norwich, is so suited for transformation of continuous currents that it need exists for going further a-field. There is no block the way, and there are no unforeseen difficulties to face. The machine is simply an ordinary dynamo with two windings on the armature, and the fact of commutation takes place in both windings on the same spindle, and in a part of the field where there are no lines, whilst the self induction of one circuit is that of the other, makes the machine absolutely

PRACTICAL ELECTRICAL UNITS.

BY W. R. JESSON.

In studying the principles involved in the construction of dynamos, it is necessary for the student to obtain notions regarding the units by reference to which energy and output of such machines are computed. We speak of a current of electricity as if there were an actual flow of something through the conducting agency, the real nature of the agency by which electrical energy is produced has yet to be discovered. These facts are correlated in a perfectly definite way, and one of the objects of electrical science is to formulate with complete knowledge the correlation. But of the nature of the agency, of the cause producing these correlated effects, we are profoundly ignorant. We do not know anything actually flows in the conductor through which current is said to be passing, though the analogy of the flow of water in pipes and of electricity in wires is in many respects a close one. What we do know is that the effects with which the electrical engineer has to deal are for their cause a common agency. When these effects are manifested, we conventionally ascribe their ap-
proach to electricity or to an electric current, these expressions being little more than a confession of ignorance as to their real cause. Analogy justifies us in treating electrical phenomena as if produced by a fluid in the conductors. For practical purposes we assume that electricity is a fluid actually flowing as a like water in pipes, but for practical purposes the idea is helpful to the student, the language of science is based on it; but after all it is but a convenient expression. There may be no current at all in the conductor, but no harm is done if, while assuming the existence of a current, and treating our facts accordingly, we remember that such treatment is adopted purely as a matter of convenience. Bearing this in mind, we proceed to the various electrical units employed by practical

engineers.—With some of the effects produced by electric currents the reader is doubtless familiar. If a magnet is brought near a conductor in which a current is flowing, the magnet will be magnetised. If a suspended magnet is brought into the vicinity of the conductor it will be deflected. If the current is sent through a platinum wire, the wire may be raised to a high temperature. Lastly, if the conductor is a liquid it suffers chemical decomposition as the current flows. The quantity of electricity flowing

can be determined only from the magnitude of the effects produced. We cannot see electricity, nor can we measure it directly, but we can see the effects and measure the pull of a magnet, the force deflecting a needle, the heat generated in a wire, or the amount of chemical decomposition. Electrical quantity might be expressed in terms of either of these effects, but in selecting a standard method by which measurement can be made, it is necessary above all things that the apparatus employed shall be capable of easy reproduction. For this reason it is convenient to define the unit quantity of electricity in terms of the amount of chemical decomposition produced. If a current is passed between two silver plates immersed in a 25 per cent. solution of silver nitrate, one plate gains in weight from the deposition of silver an amount proportional to the quantity of electricity passing. This gain is independent of the size or shape of the containing vessel, and also independent of the size or weight of the silver plates. Manifestly a standard of this kind can be reproduced at any time, and the practical unit of electrical quantity has been defined as the *Coulomb*, which, in passing between two plates in a 25 per cent. solution of silver nitrate, will deposit on one of them 0.17253 grain of silver.

2. *Current*.—The term *current* introduces into electrical measurement the idea of time. A coulomb is a quantity, it is therefore independent of time, and may take a year, a week, or a day, to pass through the conductor. Besides the unit of quantity, we require a unit rate of electric flow, or, more briefly, a unit current. Current simply means the rate at which electricity progresses along a conductor. The unit of current is the *Ampere*, which is defined as one coulomb per second. We speak more frequently of amperes than of coulombs, because generally we require to know the rate at which electricity is flowing at the moment of observation, and not the total quantity which has passed, say, after an hour or a day. It will be understood that by current in amperes is expressed the number of coulombs passing per second; thus, if we say the current is 20 amperes, we mean that in each second 20 coulombs pass through the instrument by which the measurement is being made. There exists between coulombs and amperes a relation similar to that existing between "gallons" and "gallons per second." The former is a quantity, the latter is not a quantity, but simply a rate of flow. Though in electrical measurements quantity is expressed in coulombs, rate of flow is not expressed in coulombs per second. The term ampere is employed instead, probably because rate of flow can then be expressed by one word instead of three, which saves the electrician's time.

The *direction of current* has been arbitrarily fixed with reference to the phenomena produced. It is said to flow in one direction or the other accordingly as a needle magnetised in a definite direction deflects to the right or left when occupying a particular position relatively to the conductor; or according to the direction of the magnetism produced in a piece of iron occupying a certain position in its vicinity; or accordingly as the silver is deposited on one or other of the two plates immersed in a silver bath. If the current flows through a conductor arranged to produce all these effects simultaneously, it will be found, on reversing the connections at the battery or other source of current, that all the effects are reversed. The magnetised needle is deflected to the opposite side, the direction of the magnetism is reversed in the iron, and in the silver bath the deposition is on the other plate. These facts justify us in assuming not only that electrical phenomena are caused by currents in conductors, but that these currents may be made to flow in either direction. Accordingly, with reference to silver deposition, we assume the direction of the current to be that of the silver in the bath. That is, the electricity flows towards the plate on which the metal is deposited.

(To be continued.)

ELECTRIC LIGHTING BY THE TOWER SYSTEM.

The use of high masts or towers for electric lighting purposes has not gained much favour with electrical engineers in England. Our towns, in fact, are not built so

as to permit of such a system being generally adopted, yet, perhaps, it might be found advantageous in many cases. Our nearest approach to American practice is, perhaps, in lighting docks and railway yards. We give below a description of the towers as used in Detroit, from our American contemporary *The Engineering and Building Record* :—

This question involves the following points

First.—A form of construction of towers that will require minimum horizontal space for base, be inaccessible to boys climbing, and offer least obstruction to view along the street.

Second.—Strength to resist high winds.

Third.—Ready means of ascending to the lights, so that an attendant may care for the lamps without breaking the circuit.

Fourth.—Perfect accessibility of all parts for frequent inspection and painting.

Fifth.—The proper height for towers in order to yield the best practicable results, i. e., to enable the light to reach its effective limit without unduly robbing its immediate surroundings.

The system of electric lighting from towers is of very recent date. Their construction has been subject to gradual change and development.

At the outset a square pyramidal tower was most used, made with inclined posts at the corners, united by horizontal struts and braced both in the plane of the sides and horizontally. These horizontal braces prevented the ready arrangement and operation of an interior elevator, so resort was had to a triangular tower similarly braced on its exterior faces, but requiring no interior bracing. This left free space for an elevator, but, in order to insure strength, the tower was tapered from the top to the base, so that with an altitude of, say, 150ft., the spread at the base was about 28ft.

This formed no great objection where the tower could be located in a park or unoccupied public square, but to light a city or town these towers had to be located at street corners. It was found necessary, therefore, to have the tower span the street or a sidewalk, so that one corner of the tower might rest near the corner of the street, and the two other corners of the tower rest adjacent to the buildings. This was unsightly and inconvenient, as frequently in cities the space between the sidewalk and the building is occupied by vaults or openings, and tower foundations placed there would often be very much in the way, necessitating the shifting of a tower location from a point where it ought to be to some other locality where it is possible to erect it.

Again, with a pyramidal tower not guyed, the wind pressure caused great strains, and required heavy members, and necessitated frequent adjustments and repairs. Assuming the same wind pressure per foot of height on the pyramidal tower as is permissible for the prismatic one, and that the former is not guyed, and that the latter is perfectly guyed, then for equal dimensions the unguyed tower would be strained at least four times as much as the other for the same wind pressure.

The development and improvement of pyramidal and other forms of tower gradually led to that here illustrated.

It is essentially a triangular prism, 6ft. on a side, built in 17 vertical sections, each 8½ft. long, supported on a single base column and guyed at two points. The centre lengths of all sections are equal, and members, to a considerable degree, interchangeable.

The foundation is generally located just inside the angle of the curb at the street corner, and consists of a double platform of two inch oak plank, laid crosswise, carrying a pier, three feet square, of hard burned brick set in a mortar of hydraulic cement and coarse sand; the pier is capped by a stone, 3ft. by 3ft. by 6in., that receives the base casting, the latter secured by six 1½in. anchor bolts through the masonry, and bearing on an iron ring beneath the platform. A tubular column, 14ft. high, screws into the base casting and receives struts at the top, connecting it with the prismatic tower. A light elevator platform runs in the interior of the tower, and is carried by a single endless cable passing over a fixed upper sheave and a lower sheave attached to an adjustment lever, pivoted at the short end and counter

weighted on the free long end. The outer part of the cable carries a counterpoise nearly balancing loaded elevator. Two stationary guide-cables pass through the car and are engaged by a clutch which holds the elevator stationary and only permits ascent or descent when released by pressure of the occupant's foot.

The towers have suitable lower and upper platforms with railings, and mast and arms for the lamps. All the compression members are of best lap welded tubing, screwed into connection blocks of first quality malleable iron, that have ribs to which are bolted the forked ends screwed to each end of all the wrought iron diagonal rods.

There are two sets of four guys each; one leading from a point 17-ft. below the upper platform and the other from a point 34 ft. lower down on the tower. The guys are each ½in. galvanized wire cable, connected by a turnbuckle to an eye bolt in an oak post 1½in. square by 15ft. long that is set vertically 6ft. in the ground at about 150ft. from base of tower and receives two guy ropes in the same vertical plane. The iron work is painted one coat of asphaltum, and the posts two coats of lead.

The towers are erected by first putting together the top section, then hoisting up and building on the next beneath it, and so on until completed. The weight of a complete tower, elevator, &c., including guy ropes, is about 7,200lbs.

The entire wind surface, including lamps, hoods, and mechanism, is calculated at 83 square feet, but this should probably be increased 50 per cent. for oblique and indirect exposure.

This form of tower has been subjected to terrific storms. At Evansville, Ind., twelve of them were subjected to three cyclones, one of which destroyed large numbers of houses, barns, and shops, and, in fact, demolished some of the heavy business blocks in the vicinity of the towers. The towers were not injured in the slightest degree. The other storms were likewise very destructive of other surrounding property. They have withstood very severe storms at Detroit, Mich., where 122 of them have been in service for four years. None of them have ever sustained the slightest injury, nor have they required any repairs; not even a bolt or nut has required tightening or adjusting since the towers were erected.

In the matter of the proper height, exhaustive experiments show 150 feet to be most satisfactory. Increasing this height impairs the illumination near the foot, and does not perceptibly increase the total lighted area, while diminishing this height diminishes the illuminated area and affords unnecessary brilliancy at the base. By reason of very lofty buildings in the immediate surroundings, a height of 175ft. might be in some instances desirable.

The towers should, so far as practicable, be arranged in a triangular system. The distance apart in business sections may be 1,200 to 1,500ft.; in the best residence sections, such, for instance, as may be found in Detroit at a distance of half to three quarters of a mile from the business centre, the towers may be 2,000ft. apart, and in the less densely populated sections and suburbs, they may be 2,500 to 3,000ft. apart. Thus at Detroit, Mich., 21 miles of territory, having about 4,000 street intersections, is thoroughly and brilliantly lighted by 122 towers, and there are no gas or naphtha lights within the corporation limits.

In a general way, towns of three to six thousand inhabitants, occupying, say, a square mile of space, may be thoroughly lighted in every quarter by seven towers, one at the centre and six at the angles of a hexagon, the towers being 2,000ft. apart.

So, also, an excellent illumination may be had by five towers, there being one at the centre and four at the angles of a square, the towers being 2,000ft. from the middle tower, and where greater economy is desirable there might be four towers, one at the centre and one at each of the angles of a triangle, and about 2,000ft. from the centre tower.

In all cases it is recommended that the towers should have but four lights of 2,000 candle power each. The central tower might have six lights of 2,000 candle power. More lights will not materially improve the effect at a distance from the tower, while a less number of lights will scarcely afford illumination sufficient in the vicinity of the tower.

All spaces are lighted by the tower system front yards, back yards, alleys, and streets; and in street lighting alone the four lights on a tower will do the service which would require 16 to 20 lights on poles, while the pole-lights will illuminate only the streets and not the yards and alleys.

A number of towers serve to produce an atmosphere of light so blended in every direction as to neutralize the shadows, so that dense shadows exist in no quarter, giving the effect of moonlight over the entire area.

The Detroit Electric Tower Company was the pioneer in this work, and has profited in the construction of this tower by a very expensive experience. It has erected a large number of pyramidal towers in eighteen or more cities throughout North America, but since it produced this new type of tower here illustrated, based upon its large experience, it has urged them to the exclusion of all other styles, and has already erected them in Detroit, Mich., Evansville, Ind., Fond du Lac, Wis., La Crosse, Wis., Lima, O., New Orleans, La., Indianapolis, Ind., Owensboro, Ky., Council Bluffs, Iowa, and elsewhere.

It is stated that these towers, with 11,000 candle-power lamps, give an illumination at 200ft. and 1,500ft. equal to that from a gaslight at 7ft. and 57ft. respectively, assuming the latter at the rather low value of 16 candle power. As these results are proportionate to the inverse squares of the distances, they are probably nearly correct, except as influenced by special local conditions.

Detroit, Mich., is lighted from 122 150 foot towers, costing, at list price, \$220 each, about \$112,000, allowing 5 per cent. interest and 2 per cent. for painting, etc., this gives \$7,810 cost of yearly maintenance. In 1886 the Electric Light Company's bid for furnishing lights was \$87,500, making a total of \$97,110. The gas companies made a competitive bid of \$40,000 for the entire lighting, which was rejected.

For the drawing from which our illustration is made, and the data for the above article, and for courtesies extended to our representative while investigating the subject in Detroit, we are indebted to Edward W. Pendleton, Esq., Secretary Detroit Electric Tower Company.

ON SOME POINTS IN RELATION TO SECONDARY BATTERIES.

(Being a Lecture delivered to the Hanover Square School of Electrical Engineering, by **DISMOND G. FITZGERALD**.)

According to Dr. Vander Weyde, Gantherot, in 1801, was the first to discover that the electrodes through which a voltaic battery has been discharged become capable of producing a reverse current. In the same year, Erman pointed out that the electrode connected to the positive pole of the charging battery becomes the positive pole of the secondary couple, and Ritter decomposed water by a current from polarised electrodes. In the two following years, Ritter constructed secondary batteries with plates of considerable size, and experimented with electrodes of copper, tin, zinc, lead, iron, bismuth, brass, silver, gold, and platinum. But, although five or six varieties of secondary battery were described in 1805 by Izarn, in his *Manuel du Galvanisme*, the credit of being the first to observe the peculiar properties acquired by electrodes of platinum has been given by Gavarrat and others to De la Rive, whose paper on the polarisation of electrodes will be found in the *Annales de Chimie et de Physique* for 1825. We will now briefly illustrate these properties by an experiment.

The lecturer here passed a current through an electrotype cell formed of two platinum electrodes immersed in dilute sulphuric acid, then, obtaining a deflection on the galvanometer by connecting the electrodes to its terminals.)

The explanation of the effect observed, viz., that the anode condenses upon its surface a layer of oxygen, whilst a layer of hydrogen is deposited upon the cathode, was confirmed by Matteucci, who obtained the same effect by bringing one of the plates into contact with gaseous oxygen and the other into contact with gaseous hydrogen. The question had been previously elucidated by Grove, by means of his well known gas battery.

Wheatstone, in 1843, constructed a secondary battery of very high electromotive force with negative elements of platinum coated with lead peroxide, and positive elements of potassium amalgam; and, ten years later, Siemens experimented with carbon plates coated with oxide of lead, to be converted into peroxide by the passage of a current. I have found, however, that this conversion cannot be effected by means of any form of carbon that I have tried, as the carbon itself becomes oxidised and disintegrated.

But it is to Gaston Plante, who first constructed his secondary battery in 1859, that the credit is due of having demonstrated the great advantages of lead, both for the negative and the positive elements of a secondary battery. These advantages will be to some extent illustrated by substituting strips of lead for the platinum strips used in our previous experiment, and noting both the degree and the steadiness of the galvanometric indication of the electromotive force brought into play by the passage of a primary current from one to the other electrode through an electrolyte of dilute sulphuric acid.

(Experiment shown. The deflection was reproduced after the couple had been short-circuited for a few seconds.)

An extended experience of Plante's battery brings into prominence an advantage equal in importance to that of a high and steady e.m.f. due to the layer of peroxide of lead formed at the surface of the positive electrode, which becomes the negative element of the secondary couple. It is that the positive element of this couple is insoluble in the electrolyte, and that the layer of sulphate of lead with which its surface becomes coated is provided only that the layer does not become detached from the metal readily and most economically reconvertible into metallic lead. The complete absence of the saline efflorescence, with which the users of zinc batteries are but too familiar, is worthy of high appreciation; but the fact that there is no waste or loss of material in working a lead secondary battery—the fact that a spongy lead positive may, after use, be restored to its original condition merely by returning to it, with a slight percentage in excess, the electrical energy it has developed—is one that can be duly appreciated only by those who are called upon to carry out electrical applications on an extended, and necessarily therefore, on an economical scale, and who have expended time and patience in the endeavour to effect the economical recovery of zinc converted into sulphate in a primary or a secondary battery.

Important and suggestive, and also very perfect as a laboratory appliance, the simple arrangement of Plante is ill adapted for general practical applications by reason of its comparatively low storage capacity, even after it has been "formed" by a lengthy series of successive charges and discharges. In effect a pound of lead in Plante's battery will give us only about four and a half watt hours of electrical work, whereas we may at the present time obtain from 15 to 18 watt hours for the same weight of metal more completely converted into "active material." It is stated that, so early as 1861, the late Prof. Kirchhoff, with a view to remedy the practical shortcomings of the Plante cell, constructed batteries with alternate plates of spongy lead and peroxide. In 1863 the present speaker, being then editor of *The Electrician* (old series), insisted on several occasions upon the use of peroxide of lead, in contact with platinum or lead, for the negative element of the battery. The following extract from an article addressed to *The Student*, in the issue of that paper for March 20, 1863, may be of some interest, if only from the fact of its containing statements which may be advantageously corrected or amplified in the light of our present knowledge:—"The great power of the secondary combinations we have referred to is due to the presence of the peroxide of lead in contact with the negative element in these combinations. This substance, as was pointed out by M. de la Rive, surpasses even nitric acid in its affinity for hydrogen, and, for this reason, a couple constructed with a negative element of platinum, surrounded by a mixture of dilute sulphuric acid and the peroxide of lead, and with a positive element of amalgamated zinc in dilute sulphuric acid, is more powerful even than the couple of Grove. And, when lead instead of platinum is used for the negative element, the power of the couple is but little diminished."

This concluding statement, made by me a quarter of a

century ago, receives a *prima facie* confirmation from the results obtained in the present day by our largest manufacturers of secondary batteries. I must admit, nevertheless, that it is altogether deficient in accuracy, as actually worded, being based upon insufficient experimental grounds. It is in great measure disproved by the two experiments now to be shown, which, when taken in conjunction with a third experiment also to be performed, lead to conclusions of considerable practical importance. (Experiment shown, as follows):

We first take a strip of platinum and surround it with electrolytic peroxide of lead (obtained from worn-out E.P.S. negative elements) contained in a porous vessel and moistened with dilute sulphuric acid. This we oppose to a positive element of amalgamated zinc in dilute sulphuric acid. From the deflection indicated on the scale you will perceive that the initial e.m.f. of this miniature couple is not far short of two and a half volts (2.469 v.). Let us circuit the couple through 10 ohms for a minute, on breaking the circuit you see that in a few seconds the spot of light moves nearly to its original indication. There is only a slight polarisation of the negative element, the effect of which soon disappears. But when we circuit the couple through 10 ohms for two or three minutes, the polarisation is much more marked, and the recovery is much slower. We have grounds for suspecting that platinum and not peroxide of lead, although the latter is a simple conductor, is the effective negative element of the couple. The electrolytic path to the platinum is of less resistance than that offered by the peroxide in its actual finely divided condition. Hydrogen is therefore set free at the platinum surface. Now there are two ways in which the hydrogen so liberated may become oxidised, and the platinum "depolarised." The hydrogen coated surface may become the positive element of a local circuit in which the peroxide is the negative, in this case there must be a good conductive contact at one or more points between the elements of the local couple, and the depolarising action, as we shall presently see, is very energetic. Or the negative element may be depolarised by the layer of oxidising material in immediate proximity to it, in this case the depolarising action will cease when this layer has yielded up its oxygen—unless the negative element be moved so as to bring it in proximity to fresh oxidising material. Let us so move our polarised platinum negative immediately the original deflection is reproduced: the element has become depolarised. But, unless we can adapt to the cell some contrivance for continually moving the negative element, it is evident that we have not here the conditions under which a strong and steady current of electricity can be obtained. The physical condition—the coherence, the structure, the specific conductivity in mass of our depolarising agent, appears to be a matter of great practical moment. This is the first "point" to which I wish to direct your particular attention.

In our next experiment, I substitute for the platinum a strip of metallic lead, also surrounded with the electrolytic peroxide, and opposed to zinc. The deflection now obtained indicates an electromotive force of about 1.11 volt only. It is obvious that metallic lead, and not the highly negative peroxide of the metal, is here the effective negative. Note that the deflection is augmenting—a fact that, under the present conditions, is evidence of an increase of e.m.f., due to some action (a coating with sulphate) taking place at the surface of the lead. And here I have to impress upon you a second point, viz., that lead, in imperfect contact with peroxide of lead i.e., in contact only with detached particles of this conductor, and in contact also with the electrolyte—is the effective, but is very far from being an efficient, negative of a couple analogous to that which we are now testing.

Now, a question which suggests itself and which I feel called upon to answer—is, How came I to state that "when lead instead of platinum is used the power of the couple is but little diminished?" My explanation is that, in the experiment from which I arrived at a too hasty conclusion, the peroxide was very closely packed around a sheet of lead which had become superficially peroxidised by being used as an anode in "charging up" the partly reduced peroxide. Under these conditions I obtained results which certainly compare favourably with those we have just

witnessed. Putting aside for the moment the question of the compactness of the peroxide, let us superficially peroxidise the strip of lead used in the last experiment. It will now be a Plante negative element of very small capacity. It will, we know, give with lead (spongy lead, if any applicable current is to be supplied by the couple) an e.m.f. of about two volts; and with zinc, as we shall now see, it will give an e.m.f. nearly the same (about 2.45 volts) as that obtained with platinum surrounded by electrolytic peroxide of lead. Placing the peroxidised strip in contact with this material will of course neither increase nor diminish the initial effect. The question is whether, when we circuit the couple, the effect due to the superficial layer of peroxide upon the lead strip will be supplemented by the pasty mass of peroxide and acid contained in the porous vessel. I think you will not need to await the result of the experiment in order to answer this question. We have now circuited the couple through 10 ohms for little more than a minute; and, on breaking this circuit of low resistance the e.m.f. has, you see, fallen to about half its initial value (1.30 v.). Nor will you have any difficulty in explaining this result. The effective negative of the couple is simply the peroxidised strip. This is in contact with electrolyte on the one hand, and on the other hand it is not in simple conductive contact with the mass of peroxide surrounding it, so that, when the superficial layer of peroxide has become exhausted, the negative is no longer an unpolarisable conductor, and no local circuit in which hydrogen is virtually the positive element is effective in producing depolarisation. Any slight effect of depolarisation that may occur is due to the detached particles of peroxide in immediate proximity to the negative element. And now I have to formulate a third point of practical importance in connection with secondary batteries, viz., that lead, coated with a superficial layer of dense peroxide, which latter is in contact with an electrolyte, and also in imperfect conductive contact with a further portion of peroxide of lead, acts as an efficient negative element only so long as the dense superficial layer remains unreduced. The necessity of a certain degree of compactness, or better, of coherence, in a mass of peroxide of lead intended either to act as an unpolarisable negative, or to be brought into contact with a conductor with a view to effect its depolarisation, has, probably, I think, been already recognised by some, at least, amongst those whom I have the pleasure of addressing.

Continuing our brief chronological survey, it was in 1881 that Camille Faure constructed the secondary cell which, in consequence of Prof. Sir W. Thomson's letter in *The Times*, created such a stir in the financial if not in the scientific world. Faure's accumulator, as you are aware, was formed of flat or spiral plates of lead coated with red lead, which was kept in place by parchment paper, and felt. The red lead—sesqui oxide of lead (Pb_2O_3) with excess of oxide—was, of course, reduced to spongy lead at the cathode and peroxidised at the anode in charging, the peroxide being initially in a somewhat compact form. That it was a mistake to use red lead instead of the protoxide at the cathode is very obvious, since it involved the electrolytic generation of considerably more than an equivalent of hydrogen to obtain the equivalent of spongy lead. But it is susceptible of demonstration—and the statement embodied one of the points I would wish you to note, though I do not purpose to give the proof at the present moment—that the use of red lead at the anode was a greater mistake still: for not only is the peroxide of lead already existent in red lead inefficient as a depolariser in comparison with electrolytically generated oxide, but the former, by diluting the latter, impaired its homogeneity and compactness, and thus rendered the working of the battery somewhat uncertain. In careful hands, no doubt, the Faure cell often gave results which, in the early portion of the present decade, were very encouraging if not surprising. Thus Profs. Ayrton and Perry obtained from it 6.75 watt hours per pound avoirdupois of lead employed in its construction. Other experimenters, however, obtained disappointing results, by reason mainly of a large proportion of the depolarising material being practically inert. That this should be the case will not, I think, appear to you altogether mysterious when it is

stated that the material in question was often found to be in the condition of a pasty mass. When it was ascertained, moreover, that a rotting of the felt occurred before the battery had been very long in use, the cells of Faure—undoubtedly the initial step in a great practical application of a scientific principle—entirely ceased to compete with subsequently devised forms of accumulators, of which the most prominent by far is the E.P.S. cell, with which you are already familiar.

I have no intention at the present moment of entering upon a critical consideration of the E.P.S. storage battery, and the points in connection with its working, which I will now mention, are perhaps already well known to you. These are, first, that the active material peroxide with a percentage of sulphate of lead in the negative grids should be, as I believe it now invariably is, not only very compact, but also possessed of a considerable amount of coherence, and of a structure which allows the plugs to become reduced to a lower degree of oxidation, with production of sulphate of lead, without contraction, and of the partly reduced material becoming peroxidised without sensible expansion. And, secondly, that the metallic lead of the negative grids, when these are properly charged, becomes coated with a dense and almost impervious layer of peroxide—a protective layer which should always be maintained intact by avoiding a complete discharge of the negative plates and by keeping them fully charged, excepting, of course, when the battery is actually supplying a current.

By keeping this latter point in view, the positive as well as the negative element will be maintained in an efficient condition; the complete conversion of portions of the spongy lead into non-conducting sulphate almost impossible to reduce again to the metallic state is avoided; and the durability of the battery greatly extended. The principle of working was, I may mention, first pointed out and insisted upon by Messrs. Drake and Gorham. Our concluding experiments will have some bearing upon the E.P.S. as well as other forms of battery.

Reverting now to the point which was deferred—that of compactness in the peroxide as affecting its action as a depolariser, we need not take the trouble to ram the powdery peroxide tightly round the platinum or the superficially peroxidised lead strip; for I have here a fragment of peroxide of lead in the compact and coherent form in which it is known as *lithanode*. By means of an ebonite screw, I will attach this fragment to the platinum strip, so that the two will be in contact, whilst the greater portions of the platinum surface is left uncovered. Now, if we employ this arrangement as the negative element of a couple, which portion of it will be the effective negative? or will both portions act as cathodes in collecting the current?

We might easily, if time allowed, demonstrate that the latter question must be answered in the affirmative; for, if we greatly extend the platinum surface, the internal resistance of the couple will be considerably diminished, and a similar diminution will occur if we extend the lithanode surface. But, now, will not the platinum surface become "polarised" by hydrogen, and thus our negative element be rendered inefficient? That is a question, I think you will see, which is dependent on the conductivity of the mass of peroxide and the perfection of the contact between it and the platinum. Let us test our compound negative opposed to zinc in dilute sulphuric acid.

The deflection indicated on the scale corresponds, I think, to 2.44 volts. But now I will circuit the couple for two minutes through 10 ohms. Will the e.m.f. fall to about half, or be diminished by 20 per cent, or less, think you? See, it has diminished only 2 per cent, it is rising, it has reached the original value within 1 per cent. We will circuit the cell for five minutes, whilst I am attaching a fragment of the coherent peroxide to our superficially peroxidised lead strip. Now I break the short circuit and you see the spot of light on the scale quickly reaches nearly to the original deflection. This means that the local depolarising circuit—from hydrogen layer to peroxide through the electrolyte, and from peroxide to platinum by simple contact—must be very energetic. This fact, of considerable

practical import, may be taken as another of the points to which I would draw your attention.

I will now take as the negative of the couple the peroxidised strip with fragment of lithanode attached. Observe that the deflection indicating the initial e.m.f. is quite as high as in the former case. We will now circuit through 10 ohms for a couple of minutes. On breaking the circuit you will see that the deflection does not "pick up" quite so readily as in the former case. Still, the e.m.f. now indicated is nearly 2.4 volts. But now, if we circuit the couple through 10 ohms for five minutes, the effects of polarisation is much more evident. Our negative, moreover, begins to act irregularly. The peroxide on its surface becomes reduced, a local lead peroxide couple becomes formed, and then the lead strip becomes coated with sulphate, and ultimately is corroded through and destroyed. The point for you to note in this case is that when you construct a negative element in which superficially peroxidised metallic lead is in contact with other peroxide, the latter only should be the effective negative, i.e. the superficially peroxidised metal should be as far as possible prevented from making direct contact with the electrolyte.

You will no doubt be interested to know by what means chemical and electrochemical peroxide of lead can be produced in a dense coherent and conductive form. I will therefore conclude by briefly describing the patented process by which lithanode is manufactured.

(The lecture was concluded by a description of the process of manufacturing *lithanode*, embodied in patent No. 4671, 1885.)

THE THREAD BRIDLED MICROPHONE.

The firm of P. Jenisch and Behmer, of Berlin, is introducing a new microphone in which the distinctive characteristic is that a more steady contact between the carbon pieces is obtained by means of the tension of a thread. A front view of the apparatus is shown in Fig. 1, and a section in Fig. 2. A ring of iron, E, is fixed to a plate, P, and

Fig. 1.

Fig. 2.

carries a membrane, E, to which are screwed two carbons, K. The points of the three carbon cylinders, W, W₁ and W₂, bear somewhat loosely upon the latter. The instrument will act as thus constructed, but is materially improved by a novel system of applying to these cylinders a slight pressure by means of threads, the nature of which is not specified.

One or several threads (the figure shows two) are passed around the carbon cylinder, so as to apply a pressure alternately in opposite directions. The pressure upon the membrane is thus diminished, and it consequently vibrates more freely, and can be arranged so as to give greater sensitiveness to the instrument. The play of the carbon cylinders being limited by the tension of the threads, a greater distinctness of articulation is said to be obtained. It is stated, moreover, that—unlike the Bell-Blake microphone—the instrument as thus constructed does not need re-adjustment from time to time when in use.

ELECTRIC LIGHT TOWERS.

THE ELECTRICAL ENGINEER.

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our last number a fine steel engraved Portrait of E. GRAVES, Esq., President of the Society of Telegraph Engineers (Institution of Electrical Engineers), was issued. In future numbers we shall give a series of Portraits of the eminent Electricians of this century, besides Portraits of Past Presidents of the Society of Telegraph Engineers. The next Portrait will be that of WOLLASTON, who flourished at the end of the last and the beginning of this century, and whose name has been immortalised by being applied to a particular form of battery designed by him. This will be followed by Portraits of PROF. D. E. HUGHES, F.R.S., and SIR H. DAVY.

THE ELECTRIC LIGHTING ACT.

Parliament meets next month, and one of the questions with a special interest to Electrical Engineers is what modifications will the Session bring forth to the Electric Lighting Act, 1882! It is easy to be wise after an event, and to declaim unceasingly that the Act referred to was a mistake; but what we want now is a general consensus of opinion and agreement both as regards destructive and constructive legislation. The Act of 1882 has not proved an unmixed evil, but its good points have long been discounted, while its bad features are still cruelly operative. Broadly speaking the Act of 1882 affects not so much what may be termed luxurious lighting as what may be called commercial lighting. It does not stand in the way of lighting an hotel, a factory or a warehouse with isolated plants, but it does more or less stand in the way of lighting a street of shops, warehouses, or ordinary dwelling-houses, so that business in such lighting has been reduced to a minimum. The loss perhaps has not been so widely felt as it might have been had not many of the dynamo factories been fairly busy with ship lighting orders, factory work, and orders from abroad. Again, it must not be assumed that had the Lighting Act been perfect, central station lighting would have progressed in England at the same speed as it has in America. The conditions here are totally different to what they are on the other side of the Atlantic.

The reasoning of outsiders upon such a question as the Act of 1882 is, therefore, apt to be wholly fallacious. They have but a portion of the facts before them, and at best can but see through the glass darkly. It is a fact that those most conversant with the subject have worked persistently to obtain an alteration in the law. Writing in 1883, his book "On the Law of Electric Lighting," Mr. Cunynghame, in the very first paragraph, uses these words: "The electric mania of 1882 has passed, and though the over-sanguine views then prevalent have been modified, enough has been done to show that electric lighting is possible at such cost as is likely to cause an extensive demand." The italics are ours. The only people who can tell how far these words were justified are the managers of the companies and firms doing an electric light business. So far as our investigations reach the enquiries have been very numerous, the resulting work comparative small. The reason almost unanimously given for this state of affairs is the impossibility of doing the work required under the terms of the Electric Lighting Act.

We may then safely assume: that there has been and is an extensive demand, that the trade is able, and willing, nay anxious to supply the demand, but cannot do so because of the legal conditions and obligations arising out of the 1882 Act.

If this is a correct view of the case, the demand for a modification of the Act seems a just one. The action of Parliament in such cases as this should be to safeguard the public and to facilitate the development of

the industry. How far these interests may be opposing interests is perhaps a question open to discussion, yet it is difficult to see where the opposition comes in. That the development of electric lighting may be antagonistic to the gas interests will not be disputed, but surely the one industry is not to be supported at the expense of the other. The gas interest has the great advantage of being in possession, and no other advantage ought to be given to it by any Act of Parliament.

We have said that the work immediately to be done so far as the 1882 Act is concerned is both destructive and constructive. It is destructive to the extent that all the clauses of that Act—the whole Act if necessary—which act so disastrously upon the industry must be repealed; and constructive to the extent that the clauses or the Act substituted shall leave the industry free to develop in a natural manner. It is far more difficult for a man to walk with fetters on his legs and shackles on his arms than with legs and arms free; so it is far more difficult to obtain an industrial success under legal trammels than without them. As Swift might have said:—"Industrial progress is a continual navigation; if we expect our vessels to pass with safety through the waves and tempests of competitive interests, it is necessary to make a good provision just as seamen lay in store of beef for a long voyage." Electric lighting companies have been forbidden that "provision," so have failed as yet to make that headway they deserve.

The experience gained by the trade since 1882 must point to certain requirements. Are they all agreed as to what is wanted? The first thing to do is to obtain such agreement at any rate upon all the principal points, while all minor points or details upon which agreement may not be easy should be relegated to the future. When agreement is obtained upon the fundamental principles, action should be taken to impress this agreement upon Members of Parliament. It will not be difficult to obtain one or even half-a-dozen members to put the requirements clearly before the House. And a Bill for the repeal of the obnoxious clauses, and their substitution by others as agreed upon by the trade, should be pressed through both Houses so as to become law as soon as possible. In all requirements it must be remembered that the best way to obtain what is necessary for the industry, is that the rights of the public should be respected. The motto might well be written—"A fair field and no favour."

ELECTRO-CHEMISTRY.

THE ISOLATION OF FLUORINE.

The isolation of the element fluorine, which has baffled the attempts of chemists for a great many years, has at length been effected by M. Henri Moissan in Paris. For several years M. Moissan has been examining the compounds of fluorine, and in his investigations has described the preparation and properties of phosphorus trifluoride, the oxyfluoride, and pentafluoride and arsenic trifluoride. He found in working with these bodies that the element fluorine was isolated

when the fluorides of phosphorus were passed over heated platinum and when arsenic trifluoride was warmed; but it was found impossible to collect the gas which was isolated in sufficient quantity to determine its principal properties. The poisonous nature of arsenic trifluoride rendered it necessary to seek some other compound on which to experiment. Finally, he found that anhydrous hydrofluoric acid, rendered a conductor by means of potassium fluoride dissolved in it, was electrolysed by the current produced by a battery of 90 Bunsen element. Under these conditions, hydrogen is evolved from the negative pole, and a gaseous body, possessing new properties and of powerful chemical activity, is liberated at the positive electrode. The electrolysis of hydrofluoric acid had been previously attempted by Faraday and Gore in this country, but these investigators had not found a suitable method for rendering the solution conductive to the electric current.

The apparatus employed by M. Moissan consists of a platinum U tube, closed at its two extremities by caps of fluor spar, through which passed the iridio-platinum wires, which formed the two electrodes from the battery. Delivery tubes are connected to the sides of the U tube for collecting the gases liberated, and the whole apparatus was immersed by a bath of methyl chloride, which, by rapid evaporation, lowered the temperature to about -50° . In the electrolysis of the liquid hydrogen fluoride, a small quantity of platinum fluoride is also formed, but with the battery strength mentioned a steady current of hydrogen and fluorine is produced, amounting to about 2 litres at each electrode per hour. As the author has shown that the free fluorine liberated combines instantly with free hydrogen in the cold and when not exposed to the light, it follows that the gas

liberated from the positive electrode cannot possibly be contaminated with any hydrogen gas. The gaseous fluorine thus prepared is colourless, and possesses an irritating odour resembling somewhat that of hypochlorous acid. It has very energetic chemical properties, sulphur and selenium both burst into flame when brought into contact with the gas, and tellurium combines with it with incandescence, producing abundant fumes of tellurium fluoride. Phosphorus takes fire in the gas, forming a gas which is absorbed by water (PF_5 or POF_3), and by potash (PF_3). Arsenic, antimony, iodine and crystallised silicon also take fire in the gas, bromine combines with it with explosive violence, but charcoal appears to be unacted upon. The so-called adamantite Boron of Deville is attacked, but with more difficulty than the silicon, but crystalline boron in a state of powder is rendered incandescent, and fumes of boron fluoride are at once produced. The metallic elements are, as a general rule, attacked with much less energy. Potassium and sodium become incandescent, forming the corresponding fluorides, lead is attacked in the cold with formation of lead fluoride, and mercury absorbs the gas completely, forming mercurous fluoride. Gold and platinum are unacted upon in the cold, but when heated to about 300° they are rapidly corroded. The gas liberates iodine from potassium iodide, and lead and mercury iodides are also decomposed with some violence with formation of a fluoride of iodine. Chlorine is liberated in the cold from a fragment of potassium chloride; and phosphorus pentachloride bursts into flame. A crystal of iodoform takes fire in contact with the gas. Dry glass is rapidly etched, water is decomposed in the cold, forming hydrofluoric acid and ozone, and all the organic compounds containing hydrogen which have been examined are violently attacked. M. Moissan has satisfac-

torily proved that the gas liberated at the positive electrode is not a mixture of ozone and hydrofluoric acid vapours, nor is a perfluoride of hydrogen, since the ratio of the volume of hydrofluoric acid to oxygen formed, when the gas decomposes water, is as 4:1, whereas if the gas were a perfluoride of hydrogen we should expect a higher ratio than this. An analysis of the gas was effected by means of bundles of iron-wire, which absorb the fluorine; and, from the increase in weight, the weight of fluorine liberated when a measured volume of hydrogen was collected from the electrode could be ascertained. We see from the above properties of the element that fluorine has chemical activities which are superior to those of all the other known simple bodies. It is interesting to notice that its position as the head of the family of chlorine elements has been thus experimentally confirmed, and its peculiar property of combining with hydrogen in the dark and without the application of heat is noteworthy as the first example of the direct union of two simple gaseous bodies without the intervention of some external source of energy.

RANKIN KENNEDY'S NEW DYNAMOS.

Verily of the making of dynamos there is no end—and this is as it should be—for the dynamo builder, like the architect, must consider the special work his dynamo is intended to perform. The manufacturer, however, has another consideration to take into account, and that is to make a profit. From his point of view too many types are an evil, and thus he aims at designing a few types for

various purposes to meet the largest demands, special machines being constructed at special prices. Mr. Kennedy has introduced one or two new types for construction in the Woodside works. The one known as type B we illustrate herewith. In this dynamo the field magnet is made of three pieces, with only one field bobbin. The core of the bobbin is made of best hammered scrap-iron, and is, in the machine illustrated, 10 inches in diameter and 14 inches long; the other two pieces are of soft cast-iron, and are of much greater cross section than the core of the bobbin. It is claimed that this construction has all the advantages of simplicity of construction, combined with compactness and extremely low magnetic resistance. The armature is built of charcoal iron discs, and the core is turned true, outside and inside, and mounted on metal spokes on a steel shaft; the outsides of the armature are usually turned up true on their shaft, so that perfect balance and truth of centring are obtained. The armature core is 12 inches long, 10 inches in diameter outside, and 6 inches inside diameter, the depth of core being thus 2 inches; the armature is wound with flat wire 5 mm. by 3.5 mm., one layer outside. The current allowed for this armature running constantly for long runs is 90 amperes. The commutator is made of solid drawn copper sections, insulated with mica. The brushes are adjustable in all directions, and the pressure on the commutator is adjusted by

springs. At a speed of about 900 revolutions this machine gives 102 volts at the terminals.

The following is a copy of a careful test by Professor Jamieson, Glasgow, of a 10-unit dynamo of this type, and which is now running continuously from dusk till daylight at Messrs. John Lowson & Sons, Haugh and South street Works, Forfar:—"I tested this dynamo on Friday, the 4th November, 1887, and had it run continuously for eight hours at full load (with the exception of about half an hour during the workmen's meal hour). The dynamo, which is a self-regulating, compound wound machine, consists of a single horse shoe magnet, with an armature of the gramme type. The core of the magnet is made of soft, hammered scrap-iron, the pole pieces of hematite cast iron, and the armature core of soft charcoal iron washers. The whole machine is exceedingly simple, strong, well proportioned, and well put together. It is just the kind of dynamo for factories, mills, workshops, and steamers, for it may be left in charge of any ordinary mechanic or fireman, with a minimum chance of its getting out of order. All the adjustable parts are readily accessible, and the armature may be removed and replaced in as short a time, and with less trouble, than almost any form of dynamo that I have seen. There is no perceptible sparking at the brushes. The commutator and the brushes, both from their construction and composition, as well as the freedom with which the latter can be adjusted, are calculated to last for a very long time. None of the parts of the dynamo showed any signs of undue heating, and the ventilation of the armature was all that could be desired. From a sample of my electrical tests, it will be observed that the dynamo gave an 'output' of 10,850 watts or 108.5 amperes, and 100 volts at 620 revolutions per minute, and that the electrical efficiency was 89.3 per cent.; which is good for a dynamo expressly designed as a cheap, practical, workshop or factory machine, and not as a special test dynamo for experimental purposes.

"With due attention to the oiling of the bearings, &c., there is no reason why this machine should not work continuously for a week or more on end, without giving the least trouble, and if the future machines made by the same firm are as carefully designed and constructed as the one I had the pleasure of testing, they should give satisfaction to the purchaser. It is a distinct improvement on their former dynamos.

Sample of Electrical Tests.

Resistance of armature, warm	= 0.4 ohm.
Resistance of magnet shunt, warm	= 20 ohms.
Resistance of magnet main coil, warm	= .03 ohm.
Current in working circuit	= 108.5 amperes.
Current in shunt magnet coils	= 5 "
Differ. of potential at dynamo term.	= 100 volts.
Difference of potential at brushes	= 103 "
Speed in revolutions per minute	= 620
Temperature of air	= 60° Fah.
Highest temperature of armature	= 140 Fah.
Highest temperature of magnet coils	= 125° Fah.

Electrical Efficiencies.

External electrical power, or "output" available for electric lighting, &c.:—

$$108.5 \text{ A} \times 100 \text{ V} = 10,850 \text{ watts} = 89.3\%$$

Power absorbed by armature

$$= (108.5)^2 \text{ A} \times .04 \text{ ohm} = 428.49 \text{ watts} = 3.53\%$$

Power absorbed by shunt magnet coils:—

$$5 \text{ A} \times 103 \text{ V} = 515.0 \text{ watts} = 4.24\%$$

Power absorbed by main magnet coils

$$= (108.5)^2 \text{ A} \times .03 \text{ ohm} = 353.17 \text{ watts} = 2.91\%$$

Total electrical power 12,116.66 watts

THE ELECTRIC LIGHTING OF THEATRES

The following is the translation of a paper communicated by Dr. G. Sous to the Société de Médecine et de Chirurgie de Bordeaux:—

The Greeks and the Romans represented their comedies and their tragedies in daylight, in their public places or in enclosures open to the sky. They have bequeathed to us excellent literary models, but we have not followed their example in the hour chosen for acting our plays. They appropriated the daytime for

their representations, and we have devoted the night to ours, thus placing ourselves under the necessity of illuminating our theatres with artificial light.

Wax, oil, and gas have successively been employed as a source of light, each in its turn being dethroned and superseded, and, in the incessant march of progress, electricity offers itself in our day as a substitute for gas-lighting.

Electricity is the illuminant of to-morrow. It is becoming perfected, it is spreading and growing common. Under many conditions it is called upon to replace gas, without, however, banishing it. It will be to gas what gas has been to oil. Lighting by means of oil has persisted in spite of gas; and gas will continue to fulfil its applications side by side with the electric light.

For some years past, towns, industrial establishments, and theatres have been illuminated by the electric light. Inventors and companies have rivaled each other in zeal to augment their sphere of action, they have seized every occasion to utilize their patents, and have brought into prominence the advantages of the processes they employ. The fire at the Nice theatre, and the more recent one at the Opéra Comique have attracted general attention as to the necessity of a system of lighting which would not expose the public to such disasters, and the electric light has apparently come forward as the only illuminant adapted for theatres.

As Regnault has well said, "Whenever a physical agent tends to emerge from the exclusive domain of science in order to receive industrial applications, the duty of the scientific medical man is to seek out and anticipate any useful or detrimental consequences due to its introduction in domestic economy."

This being the case, confining ourselves exclusively to those optical questions which more particularly interest us, we have to examine what is the electric light, what are its advantages and its inconveniences, and how we should annihilate any of its effects which might be detrimental to the eyesight.

Artificial light is obtained by raising to a high temperature a solid, liquid or gaseous body. In ordinary lighting the elevation of temperature is produced by combustion, the combustion of resin, tallow, wax, oil, essence, or gas. In the electric light the elevation of temperature is due to a current traversing a substance which offers to it a certain resistance.

As in the case of solar light, every artificial light is composed of coloured or luminous rays, calorific rays, and chemical rays. Lights obtained by combustion find in the oxygen of the air the principal source of their activity. They consequently develop a great deal of heat. The heat is the more elevated as the body is gaseous and has the greater affinity for oxygen. The combustion of hydrogen is one of the best known examples of this law. The electric light not being due to combinations with oxygen, since it can be produced in a vacuum, gives, on the contrary, few calorific rays. In presence of these data, the choice of a light is not a matter of doubt, whether from the point of view of the illumination of theatres or of the precautions to be taken against fire. That system which gives light and but little heat must bear the palm from that which, producing much heat, is also attended with flame which may set fire to adjacent bodies. Gas may become a cause of conflagration, it vitiates the air, it alters the appearance of colours, and in each of these respects it should give way to any system of lighting unaccompanied by the same detrimental effects and leaving to colours their natural tints.

The electric light being produced either by means of the voltaic arc, or by incandescence, we are called upon to establish a distinction, for the effects produced vary materially in these two methods.

ELECTRIC LIGHT IN GENERAL.

The Light from the Voltaic Arc.—Solar light, when decomposed by the prism, produces a spectrum, that is to say, a series of coloured rays, passing from red to violet in the order of their refrangibility. All artificial lights also have a spectrum, containing the same colours as the solar spectrum, and differing from it only by the difference of the extent of each coloured ray.

The best artificial light would be that which in its composition would be most analogous to solar light. In this respect the magnesium light should be placed in the first rank, for it is the one which approximates most to solar light; but it is very costly, and in practice it does not allow of an illumination continued for a lengthened period of time. Thus, magnesium lamps are not found frequently in use; they are mostly employed in the United States by photographers, as it allows of their operating as though in full daylight, either in the night time or in darkened rooms.

The light of gas and that of oil give an excess of yellow rays. In theatres the presence of these rays modifies the tints, whence the necessity of painting the scenery in a particular manner in order to obtain the desired effects, and also the use of rouge in order to give to the face a more natural appearance.

In regard to the electric light, we have to inquire what is its spectral composition, in order to ascertain whether it is detrimental to the eyesight.

In order to simplify the explanation, the coloured rays may be in a measure confounded with the chemical rays, and we may consider the violet and ultra violet rays as being synonymous with the chemical rays, since it is in these violet rays that we find the maximum of chemical rays.

According to most writers, the electric light contains an excess of violet rays; according to a minority there is an abundance of blue and red rays. Again, there are some who have assimilated the electric light to the solar light, and have considered it as a white light.

This divergence of opinion and of observation is not, I think, a matter of feeling. I believe it to be based upon observation, but upon incomplete observation. In fact, from an examination of the spectrum of a given electric light we must not draw a conclusion to be adopted as a general law applicable to all cases. Thus to act would be to commit a serious mistake, for it is necessary to take into account the conditions under which the experiment has been made, since these conditions modify the composition of the light.

The colour of the electric light is affected by three causes: first, the intensity of the current; secondly, the nature of the electrodes; thirdly, the nature of the medium traversed. It is important to know and to make note of these three causes in any experiment, and it is from not having taken them into account that different observers have arrived at diverse results. It is necessary also to take into account the mode of production—voltaic arc, incandescence.

The electric light being produced by an elevation of temperature, the greater the intensity of the current the higher would be the temperature, the resistance to the current being constant, and it is known that the colour of the light is in connection with the temperature. Figures supplied by various writers do not exactly agree, but it is admitted by everybody that the higher the temperature the greater the breadth of the luminous spectrum. Thus, for instance, at 500 deg. centigrade we have the red rays, the commencement of the spectrum, and at 800 deg. the spectrum will be complete, it will extend to the violet.

The colour of the light depending upon temperature, and this being due to the intensity of the current, it results that the spectrum of the electric light is variable, and the higher the intensity the more will the spectrum become developed. Thus, the arc lamps, which give a greater amount of light than incandescence lamps, have a more complete spectrum. Moreover, in practice, a lengthened examination is not needed in order to detect a great difference between the lights furnished by these two systems. The electrodes exercise also a notable effect. They may be metallic, or with the bases of carbon, either pure or in admixture with various substances.

Metallic electrodes being liable to fusion are seldom employed. They have, however, been utilised, when coated with carbon as a protecting agent. Zinc gives a blue light, silver a green light, and platinum a red light.

Pure carbon gives a pale light, producing a wan appearance; it contains many blue and violet rays. Usually it is in admixture with various substances, which increase its resistance and its lighting power. In order to prevent a too rapid consumption of the carbons and to insulate them, they have sometimes been separated by various substances, which have an effect upon the composition of the light. Kaolin gives a bluish light, plaster a violet tinted light, magnesium a yellow light.

We thus see that the electric light is not of constant composition, not having always an identical spectrum. It varies in accordance with causes which are well known. We need not be surprised that different data have been given by different writers. This follows from the fact that they have not operated under the same conditions.

In what category must we place the electric light produced by the voltaic arc?

In the generality of the apparatus employed, carbon, either alone or in admixture with various substances to augment its luminous power, to render it harder, of greater consistency, and of higher resistance to the current, and also to prevent a too rapid consumption, has been employed. With electrodes having a basis of carbon, the luminous spectrum can only be the spectrum of carbon—that is to say, a spectrum in which the greatest extent is occupied by its rays. The substances which may be added to the carbon will modify the composition of this spectrum—that is to say, will increase or diminish the extent of certain coloured rays such as the red, the yellow, and the blue; but the violet ray will always persist; since the added substances will not do away with the carbon, the spectrum of which will always appear. Thus, the electric light must be considered, in accordance with the statement of most writers, as a light rich in violet and chemical rays.

The nature of the light being known, we are called upon to inquire whether it may be detrimental to the eye by reason of its composition, or whether its action upon the eye is merely the consequence of its luminous intensity.

Before taking up this question, it will be as well to pass in review the main opinions which have been expressed as to the utility of, or the accidents produced by the electric light.

M. de Wecker employed the electric light in Ophthalmology,

and he declares that it agrees with his patients. It should, however, be said that our learned colleague employed a system having a feeble action, a system in which one of the electrodes is of copper and the other of carbon.

According to Mauthner, the electric light is rich in blue and violet rays, but in his opinion this is no drawback. On the contrary, the effect is agreeable to the retina. According to M. Javal there is no detrimental effect. The cases of iritis and conjunctivitis which have been indicated in professional electricians are temporary, and due to an abnormal absorption of light. This interpretation instinctively leads us to the hypothesis of fluorescence.

Who admits that the electric light irritates the retina from seven to twelve times more than would other flames of equal illuminating power.

"The electric light," says M. Frenzel, "presents from the hygienic point of view an objection which, I think, has not yet been pointed out—burning in the air, and especially in an almost closed space, it produces hyponitric ('hyponitrous') and a gas which in itself is debilitating, and which becomes readily converted into nitric acid by the action of aqueous vapour."

To become convinced of the presence of this gas, it is sufficient to smell the atmosphere within one of the more or less opaque globes surrounding the electric light. To give an idea of its effects we may quote the instance of a factory where in a somewhat large workshop, there were fourteen arc lamps. "In winter the windows of the apartment were closed, and after three hours of the lighting the air was no longer respirable, and the workmen were obliged to open the windows."

Lutinsky accuses the electric light of producing temporary myopia due to the contraction of the ciliary muscle. "Revue d'Optique," p. 125, 1881.

Observations on serious accidents produced by the electric light have been published by Nodder, Rockhiffe, Emrys John, Little and Puchs.

M. Bouchardat ended one of his conferences on lighting by these words: "All that I can say with certainty is that when I happen of an evening to traverse the Avenue de l'Opéra my eyes are strongly affected by this dazzling light and by its continual oscillations, and when I am able I am the first to put in action the tutamine of the eyes and eyelids." According to Stelling Von Caron, the electric light containing many chemical rays is really very objectionable for the eyesight. Such are the drawbacks which have been indicated, let us see how we may consider them in order to arrive at a means for their avoidance.

(To be continued.)

THE RELATIVE ECONOMY OF THE ALTERNATING AND THE DIRECT CURRENT DYNAMO.

In the paper read by Mr. Wm. Stanley, Jr., before the American Institute of Electrical Engineers, the author draws a comparison between the efficiency of the continuous and alternate current machines, and he finally awards the palm to the alternate current machine. Primarily, however, he shows that the two kinds of machines are equal in economy, by means of the following statements as to the output of each.

Direct current machines: x volts; R ohms; A amperes. Alternating current: $2x$ volts; $4R$ ohms; $\frac{1}{2}A$ amperes. Now, the above statements rest solely upon the assumption that the coils in the alternate current machine are all connected in series, in which case alone the E. M. F. generated would be $2x$ volts, as compared with x volts in the direct current machine, in regard to which latter the necessary presumption exists that half the coils are constantly in parallel with the other half. For the alternating current generator the average value of the E. M. F. generated would only be $2x$ under like conditions in the particular case, evidently assumed, that all the armature coils are connected in series. The rest follows as a matter of course, as n coils connected in parallel are with n similar coils offer one-quarter the resistance of n coils connected in a similar coil in series. The resultant deductions would be true only upon the assumption of like conditions for both.

These conditions, however, do not exist in practice, and regarded simply as mathematics, the statements are also open to criticism. It is evident that so far as the work performed in generating E. M. F., that is, the rate of cutting lines of force, is concerned, the average result is identical for the two types of machine, as the mere adaptation of a commutator for the rectification of reversed currents has no effect upon the resultant values. But the E. M. F., and consequently the current generated in the

alternating machine, is the direct result of two factors, namely, the rate of cutting lines of force and the self induction of the circuit, which last may be neglected without sensible error in the calculations for the average electromotive force in the direct current machine. But it cannot be neglected in the alternating current machine as at present constructed. The effects of self induction react at each change of field upon the moving coil, and the resultant effect is a subtractive quantity which must be deducted from the average amount of electromotive force generated. Any conclusions based upon a neglect of this important factor cannot be mathematically correct. Were there no self induction in the armature circuit, the expression for the average electromotive force E in both machines would be:

$E = 4\pi n A H$. In which

n = number of revolutions or turns in unit of time.

A = equivalent area of armature coil.

H = number of lines of force per unit area of field.

The above is the average value of the integral of

$$-\frac{dn}{dt} = E.$$

For alternate current machines a subtractive term enters, which depends upon the self induction of the circuit.

For the latter machine we have

$$E = \frac{dn}{dt} = \frac{d(AH \cos \theta + Li)}{dt};$$

which reduces to $E = \frac{2\pi n A H}{T} \sin \frac{2\pi t}{T} - L \frac{di}{dt}$;

in which is introduced a subtraction term which depends upon the self induction of the circuit, and is a function of the current flowing, i . Neglecting this term, the value of E reduces to:

$$E = 2\pi n A H \sin \theta,$$

for which the average value is $4\pi n A H$ as before.

As regards the Westinghouse machine, a further error is introduced in the assumption that the coils are all in series. Illustrations of the machine all show them connected in single multiple arc, which, so far as the equations for the E. M. F. are concerned, would simply have the effect of reducing any such machine to the form of one having half the number of fields. *Electrical World*.

EFFICIENCY AND REGULATION OF ELECTRIC SYSTEMS.

Dr. Louis Duncan, writing to the *Electrical World*, points out that, industrially, the question of electric lighting has now entered well upon a new phase. The question is no longer Is it possible? but, Can it be rendered economical? The consideration of losses is therefore most important. Dr. Duncan thus classifies the principal losses in a dynamo:

1. Friction; including friction of bearings and brushes, and resistance of air. 2. Eddy currents. 3. Loss in that end of the armature which is short-circuited by the brushes. 4. Loss due to reversal of magnetism in the armature. 5. Induced currents in the pole pieces. 6. Energy of sparks. 7. Loss in field magnet coils. 8. Loss in armature coils. These losses manifest themselves as heat.

He first considers a shunt-wound, constant potential dynamo, and the variations of these items as the load varies.

As the speed of the machine is constant, and the potential at the terminals is constant, the magnetic field is almost constant; it must be slightly stronger as the load increases, for the total E. M. F. must be a little greater as the current is greater; but for our purposes we may consider it constant. The speed being constant, then, if Morin's law holds for the sum of the tensions on the two sides of the belt, we have one constant for the friction.

The E. M. F. in the eddy current depends on the same factors that the E. M. F. of the dynamo does, and as the resistance of these circuits is constant, this loss also is constant.

The loss in the coil short-circuited by the brushes depends upon its resistance and self induction, and upon the strength and relative direction of the field. It is also affected by the current in the armature, but not to any considerable extent. These factors being constant, this loss will be constant. The loss due to the reversal of magnetism in the armature depends upon the strength of the field and the velocity of the rotation, and is therefore constant. The induced currents in the pole pieces of the ordinary shunt dynamo can be neglected. The loss would depend on the fluctuations in the current, which

would be slight. The loss by sparking should be inappreciable in well constructed machines which are not overloaded. Up to a certain load, beyond which the machine should not be run, it will be very small, varying with the adjustment. The loss in the magnet coils is nearly constant, increasing slightly with the load. The loss in the armature coils varies as I^2 . We may consider, then, that the losses in a constant potential dynamo are constant, excepting only the loss due to the heating of the armature coils by the current, or we may represent the loss in horse-power as:—

$$A + \frac{I^2 R}{746}$$

We should be able then from the measured efficiency at any load to deduce the approximate efficiency for any other load, providing the current in the armature is not strong enough to seriously reduce the strength of the field and cause sparking.

Experiments of the Franklin Institute are considered as follows:—In these the armature friction was slight since the armatures were coupled directly to the dynamometer shaft, and there was no belt to pull them up against the bearings. Indeed, it is interesting and instructive to compare the friction of the armature under these circumstances with that of the pulley of the dynamometer. The latter weighed several hundred lbs., and was tightly belted. The armature friction varied from 16 h. p. to 4 h. p. in dynamos whose armatures varied in weight from three or four to perhaps 1,500 lbs., while the friction of the pulley and the work absorbed in bending the belt was considerably over a horse-power, varying with the tension of the belt and the speed.

The figures given are from tests of two different types of dynamos. The last loads given are considerably in excess of the normal output. The results are reduced to the value of the ohm = 106.25 cm. of mercury.

EDISON NO. 4 DYNAMO.

Power applied in h.p.	4.2	7.3	12.5	14	18
Losses except $I^2 R$	1.16	1.21	1.26	1.22	1.39

WESTON 6M. DYNAMO.

Power applied	4	7	11	13	14.4
Losses except $I^2 R$.77	.73	.73	.91	1.04

In the last column of the Edison and the last two columns of the Weston machine the load was greater than that normally used, and the effect of the armature current increased the loss in the field and in sparking to a considerable extent. Within the limit of ordinary use, however, the losses on different loads may be regarded as approximately constant. The efficiency may then be expressed in terms of the power applied or

$$Ef = 1 - \frac{A + I^2 R}{\text{work}}$$

The losses in constant current dynamos vary with the method of regulation. A large number of dynamos in commercial use are regulated by shifting the brushes in such a way as to make the potential at the terminals vary with the resistance in the external circuit. Consider this case, supposing the machine series wound. The current around the field magnets remains constant, and we should have a constant strength of field but for the reaction of the armature. This will vary with the load of the brushes, but in well constructed machines it should not be great. Our losses, then, should be constant, with the exception of that due to sparking and to the loss in the short circuited coil, supposing the dynamo is a closed circuit machine. Both of these last would increase as the displacement of the brushes increases, or would be greater as the load is less. As the other losses would slightly decrease it may be assumed that the loss, taking everything together, would be nearly constant, or for our purpose we can put

$$Ef = 1 - \frac{A}{\text{work}}$$

For the classes of machines considered, then, the efficiency will be low for small loads and will increase until effects given under 5, 6, 7, and 8 become prominent, when it will decrease again.

CENTRAL STATION LIGHTING AT LUBECK.

In February, 1884, the German Edison Company asked the Senate for a licence and concession for the supply of electric light for Lübeck. This request was not granted, as the town intended to do the work itself. A committee was elected for the thorough investigation of the matter, and on the 19th July, 1886, the Senate and Council decided, after hearing the report of the committee, upon erecting an electric plant under the auspices of the State of Lübeck. Tenders for executing the work were solicited, and M. Schuckert, of Nuremberg, was given the contract in February, 1887, for the whole plant, dynamos, apparatus, instruments, and cables, and including the connections with the installations of private buildings. It was only after Easter, however, that the contractor could com-

mence with the building of engine and boiler houses. The erection of these buildings, together with the placing of the boiler, the steam engines and dynamos, and the laying of the cables and installations, took a much longer time than was at first anticipated, and the month of August came before the contractor could proceed with the erection of the steam engines, dynamos, and the electric apparatus. Simultaneously with the completion of the whole of the works in the engine house, the cable last put underground was tested. After sundry trials in the engine-house and in a small number of private buildings had been made in the beginning of the month, on the 16th of November the whole system was shown in operation, including about 1,000 glow lamps (16-candle power) and about twenty six lamps of 600-candle power to which exhibition the members of the Senate and Town Council were invited. The first trial, as well as subsequent ones, proved to be a great success, and the plant has shown itself to be well executed in all its details. The whole system was started working on November 22nd, 1887, and has earned the fullest commendation not only from the knowing ones, but from the general public. Originally the plant was only intended for a regular supply for 3,000 glow lamps (10 candle power) and 100 arc lamps (400-candle power), requiring 250 horse power. However, when laying down the plant it was thought better to have a respectable reserve, and also to make provision for the extension of the system by one-half. The underground cables were at the same time prepared so as to give sufficient conducting power for the calculated increase.

The engine house and chimney are erected in the centre of the town. The engine house is closely connected with the boiler house. Nearest to the entrance is a single cylinder steam engine, of about 50 horse power, with a wrought-iron flywheel of three metres diameter. Behind are placed four dynamos of the well known Schuckert construction. Each dynamo gives an electric current capable of supplying electricity for 700 16 candle power glow lamps. Two more dynamos of the same capacity will be fixed when the installation is extended, the foundations for which extensions have already been laid. For driving the four dynamos already fixed two large compound steam engines of 200 horse power each have been obtained, and each of these is furnished with a flywheel of 3½ metres diameter. Both engines are fitted with storage and condensing apparatus. Along one side of the engine house is placed the common driving shaft, which is driven by the engines by means of flax ropes, the dynamos being driven from the shaft by means of leather belts. The transmitting shaft is supplied with frictional clutches and pulleys, by means of which both the steam engines, as well as the dynamos, can be adjusted at will while the machinery is in motion. Close to the engine house, and separated from it by a wall, is the boiler house, in which are three of Heine's patent water pipe boilers, manufactured by Borsig, of Berlin. Each boiler has a heating area of 70 square metres. These boilers are in connection with a chimney 40 metres high. On the other side of the engine house, at the same height as the dynamos, is placed a most interesting apparatus provided with controllers and regulators. From the dynamos are cables bedded under the floor leading to the switch board, and from thence beyond they lead to two strong copper rails which take the entire current from the dynamos. With the aid of the switch board the current from any of the dynamos can, while the engines are in motion, be excluded or otherwise, without influencing in the least the current-creating power of the remaining dynamos. Am and volt meters are used to indicate current and pressure. The pressure, in spite of the occasional occurrence of irregularity in the motion of the engines is, in a most simple manner, kept at an exactly normal through resistance. The arrangement is such that two dynamos in work can be equally worked, or one may generate the whole current whilst the other remains motionless. Nine pairs of cables branch from the above mentioned copper rails which directly lead the current to the division centres. Each pair of cables is provided with a current meter, which indicates the current upon it at any time, and also with a regulator, which automatically regulates the current and keeps it at the pressure required by the consumer. By this means a double object is arrived at. Firstly, the lamps get the required current and the necessary light, whilst the plant is secured from waste through efficient regulation. The row of controlling lamps, while serving to light the premises where the light is produced, also show the quality and efficiency of the lights throughout the entire installation. By means of two volt meters, at any time it can be ascertained whether the pressure is too high or otherwise. There are nine couples of principal cables, already referred to, which lead the current from the engine house to the so-called division centres, and branch cables which lead from the division centres through the streets and supply the electricity throughout the town. Altogether there are about 10,000 metres of lighting cables laid through the principal streets, the diameter of which measures, according to the strength of the current, from 40 to 240 square metres. The city of Lübeck is the first in Germany to decide upon constructing an electric central station at its own expense.

and under its own municipal supervision, and that this step is being recognised as one worthy of imitation may be learnt from the fact that already, it is said, a great number of towns intend to follow its example.

PORTABLE VOLTMETERS FOR MEASURING ALTERNATING POTENTIAL DIFFERENCES.

BY PROFESSORS W. E. Ayrton and JOHN PERRY.

(Continued from page 23.)

This result was obtained experimentally by Professor Forbes in 1884,* but he appeared to regard it as a result that would not have been expected from experiments previously made on much thicker wires. Mr. Preece also published results,† in the same year, of experiments made on fine wires, and he also speaks of the results of experiments "contradicting" the law which he obtains theoretically. Whereas it appears to us that the current having to vary directly as the diameter, and not as the diameter raised to the power three halves, in order that *very fine* wires may be maintained at the same temperature, is in entire conformity with the true law of the loss of heat by radiation and convection, which was published certainly as early as twenty years ago by Mr. Roy.

Equation (5) becomes

$$\theta = \frac{I^2 d}{4 l_0^2 \epsilon \rho_0 (1 + k \theta)},$$

or

$$\theta = \frac{I^2 d}{4 l_0^2 \epsilon \rho_0 \left(1 + k \frac{I^2 d}{4 l_0^2 \epsilon \rho_0}\right)}, \text{ approximately} \quad (5)$$

The law of the magnifying spring is that

$$\phi = \frac{x}{r} (y - y_0) \quad (6)$$

where ϕ is the rotation of the pointer in radians, x is a number depending upon the material of which the spring is made, and has a value about 1 radian for phosphor bronze, and r is the radius of the spring.

Substituting for y from (6) in (2), we have, as

$$y = \frac{r}{x} \phi + y_0,$$

$$\phi^2 + 2 \frac{r}{x} y_0 \phi - \frac{1}{2} l_0^2 \alpha \frac{I^2 d}{4 l_0^2 \epsilon \rho_0 \left(1 + k \frac{I^2 d}{4 l_0^2 \epsilon \rho_0}\right)},$$

or

$$\phi^2 + 2 \frac{r}{x} y_0 \phi - \frac{1}{2} l_0^2 \alpha \frac{I^2 d}{4 l_0^2 \epsilon \rho_0 \left(1 + k \frac{I^2 d}{4 l_0^2 \epsilon \rho_0}\right)} = 0 \quad (7)$$

$$\text{or if } A = \frac{r}{x} \frac{d \alpha}{\epsilon \rho_0}, \text{ and } B = \frac{1}{2} l_0^2 \alpha \frac{I^2 d}{4 l_0^2 \epsilon \rho_0},$$

and if y_0 be called ϕ_0 , then

$$\phi^2 + 2 \phi_0 \phi - \frac{A}{1 + B I^2} = 0 \quad (8)$$

and hence

$$\phi = \phi_0 \left(-1 + \sqrt{1 + \frac{A}{\phi_0^2 (1 + B I^2)}} \right) \quad (9)$$

There are discrepancies in this result, due to—

- 1st. Our assuming (1). But it will be found that the error due to this assumption is not large for the usual temperatures of the instrument when platinum silver wire is employed, see F. "Correction for Temperature."
- 2nd. Our assuming ϵ to be independent of θ . If ϵ is not constant, the law (9) alters in shape. As we never use (9) for the purpose of graduating, but merely to give us some approximate knowledge of a general law, this will not affect in any way the accuracy of the instrument.
- 3rd. We have not taken into account the fact that time is needed to attain the state of equilibrium indicated by (4), so that θ might be expected to rise higher on first starting the current than its true steady value; but we find experimentally that this time is quite inappreciable with a *very fine* wire placed *horizontally*.
- 4th. Our having neglected small changes in ν due to the tensile strain in the wire. It can be proved that these are unimportant, except when ν is smaller than we are ever able to have it in our instruments.

5th. Our having dealt with certain small quantities as if they were indefinitely small.

B is found to be very small in our instruments, and when y , is very small it is obvious that the deflection ϕ of the pointer is very nearly proportional to V , the potential difference. When y is not small, the readings increase at first in proportion to the square of the volts, and then become more nearly proportional to the volts. In fact, the divisions for volts of the scale of the instrument get rapidly greater for small readings; then, as the readings become higher, the divisions become equal to one another, and if the range is high enough they become somewhat smaller again, due to the change of resistance with temperature making its effects felt.

For the sake of illustration we have drawn the three curves shown in Fig. 11, taking

$$A = .01$$

$$B = .0001,$$

and

and the values 0, 1, and 2 for ϕ_0 .

If such a spring is used that $\frac{x}{r} = 1$, then ϕ_0 is y_0 .

B. WASTE OF POWER IN THE VOLTMETER.

From the equations previously given it follows that the waste of power in watts spent in keeping a long fine wire l centimetres in length θ °C. above the temperature of the surrounding space equals

$$0.0008848 \pi l_0 \theta,$$

a value which depends only on the length of the wire and on the temperature to which it is raised above the temperature of the case, but not at all on the diameter of the wire. This result is confirmed by the experiments recently made by Mr. Evershed, who has found that about 36 watts are required to keep a wire 3.600 mm. long at a temperature of about 180° C. above the temperature of the case, whether the wire be 0.038 mm. or 0.0635 mm. or 0.0889 mm. (i.e., 1.5 or 2.5 or 3.5 mils.) in diameter. Substituting 360 centimetres for l in the above expression, and 180° C. for θ , the value becomes 180.2 watts. This is more than four times the value obtained by Mr. Evershed, and the reason may be partly due to the fact that (as already noticed in section A) we have hitherto regarded the rate of loss of heat as being directly proportional to the difference of temperature. On turning to Mr. McFarlane's paper we find his result may be expressed as follows:

Loss of heat per second per square centimetre of a bright copper ball 2 centimetres in radius for a difference of temperature θ °C.

$$= \text{Loss for } 1^\circ \text{C.} \times \theta \left(\frac{0.000168}{0.000170} + \frac{1.98}{0.000170} \times 10^{-4} \theta - \frac{1.7}{0.000170} \times 10^{-4} \theta^2 \right).$$

Instead, therefore, of writing as above the expression for the rate of loss of heat in watts required to maintain a long wire l centimetres in length at a temperature θ °C. above that of the surrounding space, it will probably be more correct to write it as something like

$$0.0008848 \pi l_0 \theta \left(\frac{0.000168}{0.000170} + \frac{1.98}{0.000170} \times 10^{-4} \theta - \frac{1.7}{0.000170} \times 10^{-4} \theta^2 \right).$$

If now we substitute 360 centimetres for l in this expression, it becomes

$$\theta (0.9883 + 0.01165 \theta - 10^{-4} \theta^2) \text{ watts.}$$

Of course we cannot expect this expression to give absolutely correct results for any values of θ , seeing that Mr. McFarlane's experiments did not extend beyond θ equal 60° C. The expression is interesting, however, as showing that, in consequence of the negative term, ϵ must be taken as having a smaller value when θ is high than when θ is low. For θ equal to 180° C., which was about the excess temperature of the wire in Mr. Evershed's experiments, the formula as it stands cannot be applied, as it leads to a negative answer; but for θ equal to 164.5° C. it gives, as it happens, almost exactly 36 watts, the power Mr. Evershed found was expended in any one of the three wires he tried.

Mr. Evershed informs us that he estimates the temperature to which the wire is raised by measuring its expansion; we, on the other hand, have found it more convenient, with our form of voltmeter, to estimate the rise of temperature of the wire by measuring its increase of resistance. Employing this latter method, we find that, roughly, 3.5 watts per foot are necessary to maintain a very fine platinum silver wire at a temperature of 200° C. above that of the case. This result is rather higher than that obtained by Mr. Evershed, and corresponds with a value of ϵ equal to about

$$\frac{0.0002}{d}.$$

* Jour. Soc. Tel. Eng., Vol. xii, 1884, page 243.

† Proc. Roy. Soc., No. 281, page 468.

‡ A New Form of Spring for Electric and other Measuring Instruments, Proc. Roy. Soc., No. 230, 1881, page 306.

In the absence of the results of experiments made for many values of θ it is impossible to say what is the exact function of θ that ought to be employed in the expression for the watts; and consequently we are at present engaged on experiments for determining this function. From what we have given, however, there is reason to think that the expression for the watts required to be spent in maintaining a long fine wire at any temperature θ above that of the surrounding space is a function of the length of the wire and the excess temperature only, and is usually, if not entirely, independent of the diameter of the wire.

C.—THE RANGE IN VOLTS.

If θ_1 be the highest temperature of the wire allowable; if V_1 volts be the range of the instrument without using external resistance coils, then, from (4),

$$V_1 = 2 l_0 \sqrt{\frac{\epsilon P \theta_1}{d}} \quad (10)$$

so that this range is proportional to l —that is, to the length of wire through which the current passes in going from one terminal to another of the instrument. Hence, if there are 10 wires, each of length λ , we can make $l = 10 \lambda$ by placing the wires in series, or $l = \lambda$ by placing them in parallel by means of a commutator.

Since, for small wires, ϵ is inversely as d , the range in volts increases directly as the length of the stretched wire and inversely as its diameter. As, however, increasing the length increases the waste of power in the instrument, it is rather by diminishing the diameter of the wire that the range in volts ought to be increased.

If a small range in volts be desired, it is better, in order to avoid waste of power, to use one thick wire than several thin wires in parallel, and this rule ought to be followed as long as the thick wire is sufficiently quick in its action.

In order, however, to obtain a great range, it may in many cases be desirable to employ a many wire voltmeter with a commutator, in spite of the fact that this arrangement does not give the instrument that is most economical in the power wasted when a few volts are being measured.

D.—THE GREATEST ANGULAR DEFLECTION OF THE POINTER.

With any given spring, it is obvious that we ought to tighten the wire and adjust the initial tension in the spring until the initial pull in the wire is q —the greatest pull to which the wire ought to be subjected—and also until we find that at the highest temperature the spring is just able to keep the wire taut. In our instruments where the wires lie nearly all parallel to one another we have these two adjustments, and also in those with the bicycle-wheel arrangement of wires, in which the outer ends of the wires may be attached to adjustable flexible strips. For the sake of easy calculation we may take the final pull in the spring as 0. Let L be the length of the spring, ϕ , the deflection of the pointer when θ_1 (the highest temperature of the wire) is reached, P , the initial pull in the spring. By the triangle of forces

$$P_0 = \frac{4}{3} q_0 = q \quad (11)$$

(If there are n wires caught by the end of the spring, say n complete diametral wires in the bicycle-wheel form, then instead of q we must use nq .)

The law of the spring is such that

$$y_1 - y_0 = r \frac{P_0 L^a}{\rho^3} \quad (12)^*$$

where r is the radius of the coils of the spring, L its axial length, a a constant depending on the material of the spring, ρ the thickness of the strip of which the spring is made; and another law of the spring is

$$\phi_1 = P_0 L \frac{b}{\rho^3} \quad (13)$$

where b is a constant like a . In fact, $\frac{b}{\rho^3}$ is the constant α used in (6).

Substituting for P_0 from (11) in (12),

$$y_1 - y_0 = r \frac{L^a}{\rho^3} \frac{4}{3} q_0 = S \frac{r}{\rho^3} q_0, \text{ say } \quad (14)$$

equation (2) is

$$y_1^2 - y_0^2 = \frac{1}{2} L_0^2 \alpha \theta_1 = R, \text{ say.}$$

Dividing by (14) we have

$$y_1 + y_0 = \frac{R \rho^3}{S r y_0};$$

so that

$$y_1 = \frac{R \rho^3}{S r y_0} - y_0.$$

Substituting in (14), we find

$$\frac{R \rho^3}{S r y_0} - 2 y_0 = S \frac{r}{\rho^3} y_0,$$

or

$$y_0 = \sqrt{\frac{R}{S \frac{r}{\rho^3} (S \frac{r}{\rho^3} + 2)}} \quad (14)$$

Substituting for P from (11) in (13),

$$\phi_1 = \frac{L b 4 q y_0}{l_0 \rho^3} \quad (15)$$

and using y_0 just found, in which $R = 2 l_0^2 \alpha \theta_1$, and $S = 4 L a q$, we find eventually that

$$\phi_1 = \sqrt{\frac{L b^2}{a 2 L a q r^2 + r^4 l_0}} \quad (16)$$

where neither of the two terms in the denominator is negligible. The observation in brackets given after (11) tells us that we may use nq instead of q in the formula if there are n lengths of wire or n complete diametral wires in the bicycle-wheel form of instrument. An examination of (16) will show how the range ϕ_1 may be made large.

The following are the deductions that may be drawn from (16) —

1st. If f be the working stress suitable for the material of the wire,

$$q = f \frac{\pi}{4} d^2,$$

or

$$nq = n f \frac{\pi}{4} d^2;$$

so that, if we desire a large maximum deflection without reference to the range of volts, we ought to use wires as thick as possible, or else use many spokes in the bicycle-wheel form. The limit to the thickness that may be given to the wires arises from the fact that the best equilibrium will only be established slowly with thick wires, so that the dead-beat character of the instrument suffers if the wires be too thick.

2nd. The greater l , is, the greater is the maximum deflection. Hence the greater the diameter of the bicycle wheel and the more numerous the spokes, the greater the maximum deflection. Also, the greater the diameter of the bicycle wheel and the greater the number of spokes, still more noticeable is the range in volts.

3rd. Diminishing the thickness (t) of the strip of metal of which the spring is made has a very great effect in increasing the maximum deflection.

4th. Increasing the length (L) of the spring increases the maximum deflection just in the same way as increasing q or nq .

5th. Diminishing r , the radius of the coils of the spring, produces a great increase in the maximum deflection.

(To be continued).

INSTITUTION OF ELECTRICAL ENGINEERS.

The first meeting of this session was held in the theatre of the Institution of Civil Engineers, Great George-street, on Thursday last, when Sir C. BRIGHT vacated the Presidential Chair, and introduced his successor, Mr. E. GRAVES, who proceeded to deliver his inaugural address, as follows:

According to the poetic mythology of ancient Greece, Minerva, fully grown and armed, sprang from the brain of Jove: Wisdom was perfect at its birth; neither study, observation, nor experience were necessary to bring it to maturity.

But the wisdom of the early civilisations dealt only with the external aspect of material things. The hidden secrets of Nature were undisturbed. The philosophers of those days fondly to look below the surface nor did they call into activity forces dormant until the moment that the researches of the investigator should stir them into life.

When that period arrived it was manifested by progress in a very different manner from the sudden growth symbolised by the myth of Minerva. First, the observance of strange phenomena, and of the fact that their reproduction, under similar or differing conditions, as the case might be, was possible. Next the discovery of distinct purposes that could be effected, by the utilisation of the same force that had given rise to the phenomenon originally observed. Then the knowledge of the means by which this force could be produced, to whatever extent it might be required or be capable of, and that when produced it could be controlled; and lastly, the combination, into a definite scheme, of the results of all these researches and discoveries, so that the principles regulating the new science might be formulated, and its leading laws made known—thus creating a basis upon which could be ultimately moulded a more or less valuable addition to the resources of the human race.

* "A New Form of Spring for Electric and other Measuring Instruments," *Proceedings Royal Society*, No. 230, 1884, page 311.

The various stages through which the growth of any original science must necessarily pass can be stated in a brief paragraph, but to realise them conditions are often required.

Electricity and magnetism, which may be regarded for our present purpose as varying expressions of the one original power, furnish a good illustration of this fact. Even now our knowledge, both of the agent itself and of the possible uses to which it may be applied, is very incomplete, but being what it is we can clearly trace its evolution.

Neglecting the earlier observers, who merely noted the existence of startling facts which they neither endeavoured to reason upon nor explain, we may fairly say that from Gilbert, of Colchester, to Faraday, three complete centuries were occupied in nearly continuous investigation of the laws that govern the action of the mysterious agents, and of the methods by which its powers could be controlled and employed. A list of names of distinguished men in all civilized countries shows that many minds cooperated in the enquiry, and added to power together, observation by observation and discovery by discovery, that mighty outcome of scientific organ, which, in many respects, has revolutionised the material world, and will still further revolutionise it.

Faraday and Joule may be regarded as the last workers and discoverers of English birth at least in the field we are considering, who tried its path with absolute devotion to pure science alone. They and their predecessors noted facts and deduced principles, they stored up a mass of observations for the guidance of their successors, but they did not seek to apply them, so as to turn the knowledge that had been gained to commercial account.

A different state of things now exists. Long prior to Faraday's time, other earnest students of electric science saw that, in realising the triumph that it might attain, benefit might be secured to themselves and to themselves alike. The hour had come when the laborer would reap the reward of his efforts, and profit by the devotion of his life to the study of Nature's laws. Since then, every distinguished electrician has applied the science he loves to some practical purpose. When success has been secured in one department it serves only as a spur to further exertions, seeing that success means reward, and thus the mounting stimulus produces greater and greater efforts, and wider and more far reaching results.

The object of the compiler of this address has been, however imperfectly, to trace the nature of the benefits already conferred upon the world by the use of electricity in some of its varied expressions, and to gauge the extent of the employment it has given by means of its operations to at least the inhabitants of our own country.

It is almost impossible to express the variety of ways in which the action of electricity is utilised. Their name is legion, and they are multiplying. Communication between distant places was the first and most extended purpose to which it was practically put. Originally its operations were confined to points separated by land only. Then, crossing rivers, channels, seas, and oceans were successively crossed, until now nearly the whole earth is bound together by subterranean chains—a kindly bondage that is another name for union. The ocean only—the Pacific—remains uncrossed, and the barren isolation will hardly be much longer preserved. One country of importance only—the Empire of China—has hitherto been reluctant to embrace the lightning messenger, but that reluctance appears to be on the verge of disappearing.

Another most prominent utilisation of electricity is for the purpose of illumination. First practically discovered by Humphrey Davy, its powers in this direction were successively made practical by Weyle, de Morion, Pichot, and Gramme, and by many eminent scientists of later date. Electric lighting has passed very many stages, differing from telegraphy, it needed a longer period of trial and experiment after its commercial application began; and it is, of course, exposed to the competition of other illuminants ever seeking, by new methods, to lessen its superiority. Economy of production is, perhaps, the great necessity for its complete development. As the light of brilliance, health, and beauty, its claims are universally acknowledged, but the commercial problem can hardly be said to be completely solved, although the steps taken in that direction give promise of a satisfactory solution being not far off: the problem of illumination is becoming understood.

Telephony, in other words, telegraphing by means of the sonorous vibrations of the human voice, and not by means of signals controlled by the human hand, came into the field comparatively recently, but has met with wide acceptance and has had a vigorous growth. It has been welcomed in all countries as a boon to humanity. The delicacy of the instruments by which it is worked is, perhaps, the source of greatest difficulty that its further development has to overcome; their sensitiveness is alike manifested to intended and unintended influences. Since their inception we have had means of observation far more delicate than any previously in general use, but we have also discovered that the influence of "induction" is apparent to a much greater degree than was before deemed probable as an interference with the practical working of electric communication for commercial purposes.

In electro-metallurgy, electro-plating, electro-typing, and the like use, electricity operates in many different directions. In some instances it is employed as a new and better way of producing the same results that were previously produced by inferior means; in some instances it is used as a novel as well as for methods employed.

The substitution of electricity for steam, water, or gas as a source of power, capable of driving mechanical engines, either stationary or portable, or heating, and the transmission of similar power to a distance from its source of origin, although successfully carried out in many instances, may be considered as yet rather in the earlier stages of experiment and growth than of those of completion. There is a wide field yet to be explored in this direction.

For medical purposes electricity is also extensively employed, but I cannot but say that I am unable to separate the wheat from the tares—the

really curative agent from the imposture—and therefore can only say it is evident that much may be done in this direction; much is already done, but the extent of the area it will finally occupy cannot yet be perceived. When the real nature of the power employed is understood, then we can better appreciate the nature of its influence upon the ailments to which the human frame is subject.

As a warning against fires that may threaten our houses, an agent employed to summon helpers to our relief, the electric current renders great service, that will, it is to be hoped, be availed of more extensively in the future than it is at present.

Electricity is also utilised to an increasing extent as a safeguard to the lives of the toilers in our coal mines charged with explosive gases. As yet it is somewhat of an uncertain stage in this respect—its use is proved, the desirability of its employment recognised, and efficient instruments for the purpose devised, but practice is yet needed to remove the difficulties in the way of its general adoption, to overcome the inertia that blocks its path.

Like the steam hammer that can strike with the weight of many tons, or crack a nutshell with a gentle tap, electricity can unite sundried continents or serve as a household convenience. For ringing the bells of our houses it has practically superseded the apparatus of pulleys, cranks, and movable wires, it can be operated over distances to which they were inapplicable. For submarine mining, blasting rocks, firing fire-bombs that cause mountains to crumble, and for the purposes of warfare, the heat-conveying powers of electricity are extensively employed.

The last of the uses of electricity that I will particularise was one of the earliest to be availed of: a species of telegraphing with a special object, guiding trains in their way, and guarding against the risk of collisions by night and by day. When steam had won its greatest victories, it was necessary that some swifter and more subtle power should be at hand to control and regulate its action. Such power was found in the use of electricity, by means of which signals are given that track and guide the moving train throughout its journey. The line of railway is divided into successive sections, into each of which a train is forbidden to enter until the electric indicator gives permission, such permission being withheld until it is announced, by similar means, that any preceding train has passed from the further end of the section, upon which its successor is allowed to enter.

I have so far specified a few of the leading purposes for which electricity is employed, but to enumerate them all is practically impossible; the sphere of its influence is widening every day, and no one can attempt to say when its ultimate limits will be reached.

Only on Saturday last I saw an announcement in an evening journal to the effect that it had been discovered that the passage of a powerful stream of electricity through sewage water effected the division of the solid from the liquid constituents of the latter. No practical description of the *œdipus operandi* was given; but the bare announcement, whatever the results, shows a new direction in which some minds, at least, hope that profitable employment for the electric agent may be found.

It is clear, however, that in the great majority of its applications electricity is used as an agent—a tool, so to speak—for producing effects hitherto obtained less perfectly and less extensively by other means. For illumination, the supply of power for plating and many other purposes to the production of which electricity is applied, means existed in one form or other before the use or value of the latter was known. The improvement, however, effected by its use in some processes has been so great that it amounts almost to a discovery, and in almost all there is still great scope for increased progress.

One of these processes may be mentioned in the case of the electric light as applied to the illumination of ships—notably in passenger steamers—at sea. The contrast between the comparatively dim oil lamps and the bright glow of the incandescent lights is so great as to make the latter really a new thing. Gas cannot, for self-evident reasons, be commercially applied to our floating palaces. Electricity has therein found a field in which it has no competitor.

Telegraphy and telephony, however, have introduced a really new thing into the world. True, the word "telegraph" was applied to an instrument—the semaphore, which preceded that which we mean when we use the same expression, but its operations were so limited—darkness or fog suspending them entirely—that no real comparison between the apparatus of Wheatstone and Morse and their so-called mechanical predecessor can be instituted. A few lines of gantry-looking frameworks, on which hung pendant legs and arms of wood, or closing and opening shutters worked by levers, stood at considerable distances from each other. The signals expressed by the persons controlling the fast machine in many such lines were noted by an observer stationed at the next machine through a powerful telescope, from the second they were repeated to the third; and so, when the light and weather permitted, they reached the final point communicated with, sometimes with very considerable rapidity. Nearly all such lines—and they were not many in England—were entirely for the Government service, chiefly that of the Admiralty. The only long private line of communication of the kind of which I am aware was that belonging to the Mersey Docks and Harbour Board from Bakenhead to Holyhead—used for signalling the arrival or departure of vessels. Imperfect as such means of communication, often interrupted, were, when their operations did succeed they were enough to show how great the advantage would be to the world in general if they could be permanently depended upon. Hence arose the efforts of Ronalds, Schumacher, and others; but the time was not fully ripe. The discoveries of Galvani, Volta, and Ersted, however, combined with the result of preceding experience, led to the construction of the telegraphs of Gauss, Weber, Schilling, and Steinhel; and finally, the endeavours of Cooke and Wheatstone in England, and Morse in the United States, resulted in the production and general use of a reliable means of long distance telegraphy, which has since been improved upon in many ways, but which in its essentials remains the same.

Now let us see what is the outcome of all this thought, inventive

genius, and intellectual energy. What has the thing they produced done for us?

Let us compare, say, 1837 when Cooke and Wheatstone first demonstrated the practicality of their system with the state of 1887.

In 1837, whenever a member of any family, however highly placed, left the shores of his native country, he was lost to his friends—he disappeared, as it were, from their lives. He might be heard of at more or less frequent intervals by correspondence passing through a slow post, but in no emergency, however great, could he be communicated with in time to admit of his taking prompt action: separation was real and its real meaning felt. For instance, in 1834 and the conditions were little changed in 1837—when the first Melbourne Administration was dissolved by King William IV., a special messenger, despatched from Brighton on the morning of November 15th, to Sir Robert Peel, then at Rome, could only carry to him the offer of the Premier'ship in ten days' time; making all possible speed he only arrived on November 25th.

At the present day not a man travel throughout the world, he holds in his hands, as it were, the strings communicating with his own home. Twenty-four hours, in practice, is an extreme period to elapse between the despatch of an urgent summons, or the communication of an important piece of intelligence, and its acknowledgment by the recipient, even at the ends of the earth. Last month Lord Hawke died at the St. Pancras Hotel. His son, and successor, was enroute in Victoria, Australia, but in a few hours he received the sad intelligence, and will be home long before he could have known of the necessity for his return in the former state of things. Take the converse of this case. A criminal fleeing from justice wishes, of course, to cut off all traces of his connection with the place whence he flies. Fifty years ago he could do so easily, a few hours' row at the start would enable him to elude pursuit effectively. He could escape by sea and know that he could not be followed for a certain number of days, and that on his pursuers arriving at the foreign shore they would find him gone—vanished into the far-spreading regions of the West or South where no clue could be found. Now let a man succeed in catching the fastest steamer that skirts the ocean, and let him do so unobserved by his trackers here; he arrives at New York, Cape Town, Melbourne or Suez, only to find the police awaiting him, and ready to return him, by the quickest available means, to answer for his misdeeds.

In some quarters there is a tendency to question whether our modern improvements have really tended to increase the happiness of the world; whether there was not more real comfort when the pace was not so fast. A recent novelist has entitled one of his latest productions—the period of which is laid in the last century—"The World Went Very Well Then," implying, of course, that the present day is, at any rate, very little better—this is not the general feeling. There may be a germ of philosophic truth in it, but mankind does not, as a rule, govern itself by philosophic ideas. It may have been possible for a merchant of 50 years ago, who knew nothing of the changes of markets or of the political occurrences that had happened which might govern them, or affect speculative risks, save on the arrival of weekly, fortnightly, or monthly mails, to be content that he was spared the worry of concerning himself every day with such matters, but now the telegraph brings him daily or hourly news on all these points he has, at least, the advantage that no catastrophe can mature during his period of ignorance, and burst on him like a thunderstorm when the periodical notification arrives. Counting house speaks to counting house, not face to face, but in effect almost as if it were so. Orders have been despatched by post to be executed in London, and the goods sent to Calcutta—a turn of the market at the latter place shows that the execution of the orders will be a misfortune, the telegraph is employed and they are countermanded, no mischief being done. Shares that are held in various parts of the globe are suddenly greatly appreciated or depreciated at one of the great commercial centres, the facts are at once transmitted by wire to the others, and all markets are, at nearly the same time, placed on the same footing. The possibility of dealing rapidly in one centre, and of perhaps reversing the operation in another, is rendered under ordinary conditions, impossible; no such coup as that by which Nathan Rothschild gained £2,000,000, by his energetic exertions to secure early intelligence of the result of Waterloo, is now possible. To a large extent individual chances are equalised at any rate so far as they depend upon the securing of rapid knowledge of occurring events. It is argued that this is an evil to the smaller firms, that houses with a large command of means can bear the cost of communicating freely by wire, and thus the possession of capital tells more heavily than before in the race of competition against the lesser houses. There is some truth in this contention, but it is but one illustration of the general tendency of modern trade, which more and more shows that success in all the wider fields of commercial life is mainly secured by the operation of gigantic concerns working with vast resources, whether wielded by a single person or by an association. Individuals enter in this struggle of competition, but the work at large profits by the increased magnitude of the aggregate business done, and the facility of rapid communication is not the least potent factor in bringing about the results we are witnessing.

In political matters the lightning messenger is not less powerful for good. Formerly, intelligence of some distant battle or movement was received at headquarters a certain day, and nothing could be heard in reply, nor any direction given, until many successive events had transpired, and perhaps irreparable mischief had been done. In its early days also, to put the telegraph in motion was not but doubtful advantage, the despatches were too brief, the orders were too short—they were often misunderstood—rarely was their motive explained. In later times it has been found possible, on sufficient occasion, to exchange by telegraph despatches as full and clear as could be transmitted by letter, and thus no ground is left for the growth of misunderstandings that might produce international evil. Formerly irritated feelings grew up, and those whose duty and desire it was to soothe them were too

late before they could apply any effective check to the popular passion that was urging either side into courses that could only culminate in war. The excitement that convulsed this country when Commodore Wilkes lately took the Confederate envoys from the mail steamer Trent and very nearly brought two kindred nations into a miserable conflict—then being then no cable connecting England with the United States—and the speedy collapse of the fierce fever that over-spread France this year, when the frontier squabbles with Germany culminated in the forcible arrest of Schœnsholtz followed later by the unfortunate shooting of French sportsmen by Germans, are instances of the advantage of the telegraph being in existence. The statesmen on either side were enabled to promptly calm the feelings that threatened much at first, but speedily collapsed when the trifling character of the unlucky accidents was understood. Perhaps the ease with which directions can be transmitted from the centre of Government to colonial governors or military commanders should be admitted to have some drawbacks attaching to it. Of course the full circumstances of any special situation can only be known to those absolutely on the spot, and it is an evil when the transmission of too detailed instructions to them destroys the sense of individual responsibility in the officers commanding abroad. The telegraph makes much possible for the minister at home, but in some things discretion is best shown by abstinence from its too extensive use. Again, to take another form of superfluous energy as an example, it was, to say the least, unfortunate that, when the British and French armies were engaged in a life-and-death struggle with the Russian for in an incident winter in the Crimea, Lord Palmerston, then Minister for War, found the single wire laid between Varna and Sebastopol convenient for despatching the English Commander-in-Chief to "take care of 'Dodd.'" His relative, Major Howdregg.

News, in its widest sense, is a very different thing now than it was formerly. A newspaper of the earlier portion of this century contained intelligence from all quarters no doubt, but it was not contemporary intelligence, nor at all regular in its appearance. From the nearest capitals of Europe it might perhaps be two or three days old only, but in the same journals that printed this news appeared articles from the most distant parts of the globe dated two, three, or even five months before. For instance, in 1837 in the Times of July 20th, there appeared news from Valencia Spain, of Carlist operations on July 15th, the semaphore having been utilised for its transmission across France, but its news being broken off because darkness had come on. On July 26th, news was published from Rome dated July 16th. On the 28th of that month, the dates from Hamburg were July 23rd, but in the same issue Constantinople intelligence of July 7 was printed. From Quebec, news to the 3rd July did not appear until 3rd of August; and from New York, May 4th is the latest date mentioned on May 29th. From Tasmania, news to January 27th was not made known until May 30th. From the Cape of Good Hope, intelligence to March 25th was not published until May 30th, and on the same day Calcutta advices to January 27th appeared. Sydney letters of December 31st, 1836, were made public on June 8th, 1837; and, in the same paper, Batavia reports of December 28th presenting appeared. Buenos Ayres news of March 19th, saw the light on June 13th.

In an earlier issue of that journal, under date of December 10th, 1837, appears a paragraph calling attention to an instance of unexampled rapidity of communication between Liverpool and New York, letters having crossed the Atlantic three times within 65 days. The vessels conveying them made unusually quick passages, and each departure took place within a few hours of each arrival, the correspondents taking advantage of them to despatch their communication without loss of time.

Since that period an entire change has appeared on the face of journalistic matters. If a cricket match takes place at Sydney, New South Wales, on December 10th, the full score appears in *The Times* on the morning of December 12th, the intervening day being Sunday, but 10 hours being represented by the difference of time between the longitudes of Sydney and London. On December 23rd, a resolution of the New Zealand House of Representatives, on the subject of Colonial Defences, dated December 22nd, appeared in the first edition of the same journal. And on December 31st, a message appeared in the second edition of the *Globe*, printed at 12.30 p.m., dated the same day giving the substance of Mr. Humboldt's speech at a banquet at Toronto the previous night. If despatched at 6 a.m., the difference of time alone would make it 5 hours later before it could reach London.

Not only events of mighty import to the interests of nations but records of comparatively trifling matters—the appearance of a popular actor, the result of a boat race and the like—are flashed across the world, and published here as they would be had they transpired in some city of our own island. The world has indeed become very small, if its dimensions are to be measured by the rapidity of knowledge in one part of the facts that occur in another.

Again as regards our country alone, a most remarkable change has occurred in the character of the press. Fifty years ago the most important speeches might be delivered a few hundred miles from London, and they appeared in the shape of a message, condensed summary the second or third day after delivery. There was no longer now when they could appear at all, and hence it was not worth while publishing them at length when they did appear; perhaps, however, this imperfect publication had the compensating advantage of lessening their frequency so far as readers were concerned. Now, if Mr. Gladstone speaks in Milford, Lord Hartington at Dublin, or Lord Salisbury at Liverpool although it may be close on midnight before their material has been completed, yet next morning the broad sheets of our early press will give us, verbatim, all that their audiences have listened to, and, in fact, the readers of London papers often know much earlier than the residents of a village ten miles from the place where the discourses were delivered what were the very expressions of the distinguished speakers.

It is not at the present day, conditions of time or distance that limit the fulness with which an oration appears the morning after

delivery in the newspapers but only the amount of popular interest which the conductors of each particular journal believe will be taken by its readers, in the speaker's words. Audiences are no longer confined to those who are present in the largest halls, on the wings of the telegraph, and by the agency of the newspapers the speaker addresses the whole world, or at least such portions of it as care to know his opinions on the subject of which he speaks.

The use of the telegraph is not at all in proportion to the population of the various localities it serves. Much depends upon the nature of such populations, on the avocations in which they are mainly engaged, and the extent to which fluctuations are liable to occur in prices of the commodities in which they are interested. A certain constant quantity, as it may be considered, of telegraphic business arises from the needs of domestic life. This is common to all centres, but necessarily varies as the mass of the inhabitants varies. From the east of London, for example, 500,000 residents have occasion to communicate by wire on their ordinary affairs much less frequently than a corresponding number of residents in the west. Speaking as a general rule the operative classes of the community have less widespread interests than those placed higher in the social scale. They receive in relation to their numbers fewer letters per head and send fewer telegrams. The employment by them of the speechless engine of communication is decidedly on the increase, but it has still great room for growth.

London is far and away the centre of greatest telegraphic activity, but the fact of its being the capital, the seat of the Legislature and of the Law Courts, the headquarters of the Stock Exchange, and so on, gives it so many special features, independent of its widespread commercial interests, that it can hardly be properly compared with any provincial town as regards the amount of business done. It may, however, be of some interest if I contrast a few of the leading provincial towns in this respect.

Taking the calculated population within the free town delivery of letters up to the end of 1896 and the actual number of telegrams originating within the same limits for the year ending September 30th, 1897, the results are as follows:

	Population.	Telegraph Messages.
Glasgow	740,000	1,444,741
Liverpool	730,000	2,268,082
Manchester	613,982	1,660,538

Exclusive in all cases of the messages collected from America and the Eastern Telegraph system, which are despatched by special wires worked by the cable companies. Upon these figures it should be remarked that the population attributed to Glasgow includes the ring of minor boroughs excluded from the city in a municipal sense. In the case of Liverpool all north of the Mersey is reckoned, but Birkenhead, largely peopled by persons interested in Liverpool commerce, is excluded. But the fact remains that the seaport possessing the largest trade of any, out of London, in the kingdom, does the largest telegraphic business. Manchester includes Salford in its number of residents and being a central point for numerous surrounding towns who look to it for guidance in commercial matters, ranks somewhat higher above the larger population of Glasgow as regards the employment of the telegraph. Further—

	Population.	Telegraph Messages.
Birmingham	420,000	672,714
Edinburgh with Leith	319,030	667,758
Bristol	319,000	582,083
Newcastle-on-Tyne	151,500	546,264
Bristol	227,127	466,412
Hull	186,290	452,821

show the comparative telegraphic pre-eminence of the seaports as compared with the subordinate capitals and the great Midland manufacturing centre, Edinburgh including Leith in its boundaries, which thereby a place of national commercial activity to its semi-metropolitan population.

Other cases strengthen the conclusion that the nature of the trade rather than the absolute volume of business must be considered in determining this comparison, thus—

	Population.	Telegraph Messages.
Leeds	296,108	337,996
Belfast	225,900	344,603
Sheffield	305,000	257,056
Nottingham	211,424	236,143
Liverpool	127,506	188,890
Cardiff	115,000	394,691
London	152,940	206,168
Aberdeen	113,212	206,680
Newport (Monmouth)	40,000	153,193

For most of these divergences and discrepancies, persons familiar with the characteristics of the various towns will easily find reasons; and I may add a few more instances.

	Population.	Telegraph Messages.
Portsmouth	132,669	154,905
Plsmouth (Disport)	96,142	185,454
Southampton	61,000	158,067
York	60,300	126,541
West Hartlepool	32,000	114,014
Oxford	44,000	86,524
London	40,340	96,721
Bath	57,600	81,126

Analysing the figures given above, we find that Liverpool, with rather more than three messages per annum per head, Newcastle-on-Tyne with rather more than 3½ messages per head, Cardiff with somewhat less, Newport (Monmouth) with an approach to 4 messages per

head, and West Hartlepool with about 3½ messages per head per annum, rank highest among English towns as contributors to telegraphic employment. It may be remarked that Oldham and Blackburn, both containing over 100,000 of population do not figure in the list of the 52 towns whence the greatest number of messages are forwarded although many are smaller places also.

In some instances apparently extraordinary results are explained by local facts. Thus the 60,500 residents of York apparently do much more business than the 91,000 inhabitants of Newcastle, a city of the same general character, 126,000 messages to 89,000, but probably the circumstance that two important race meetings are held at the former place, and the great railway station there is far more important to the travelling community than any at Newcastle, may account for the distinction. If it were possible to analyse the apparent discrepancies between the figures of other towns, no doubt there would be some simple means of explaining them.

This much may serve to illustrate the changes that the electric telegraph has wrought, and the benefits it has conferred.

(To be continued.)

THE CITY COMMISSION OF SEWERS

At a meeting of the City Commission of Sewers held at the Guildhall, on Tuesday, Mr. Graham King presiding, a report was brought up from the Streets Committee submitting for adoption a proposed arrangement with the Anglo-American Brush Electric Light Corporation for lighting a district of the City by means of electricity. It stated that for nearly four years the committee had been in negotiation with that company in reference to various proposals for the electric lighting of a portion of the City on the principle of their being afforded facilities for lighting the private premises on their line of route, and they now submitted a draft contract for lighting the district commencing from the front of the Royal Exchange, and comprising so much of the City as lies between the Foulney Church, St. Paul's Church, and the Billingsgate and Fleet Street, on the north, and Queen Victoria Street and the Strand on the south. It was proposed to have 169 lamps of 2,000 candle power at £226 each per annum, or £43,394 in all, in place of 616 gas lamps costing £22,246, the total illuminating power of the gas lamps to be about 32 times that of the present gas lighting. In the narrow parts and courts glow lamps of 400 candle power and in greater number might be substituted at an additional cost of 50 percent and 25 percent, respectively. The contract was for seven years, with power to the Commission to continue it for further periods of seven years, so long as they did not grant to other companies powers in regard to private lighting within the district. The contract might be terminated after notice in writing of ninety days of lighting and not later by the company for a month. The Commission would grant to the company the exclusive right to supply private lighting and if they terminated the contract as to public lighting the company were to be at liberty to continue their private lighting.

Mr. J. C. Bell, in moving the adoption of the report, spoke of the great importance of the matter, and observed that unless the Commission gave some such decision as was proposed in the report, electric lighting in the City must be imperative for some time to come. The cost would not be more than twice the present cost of gas, while they would have 32 times more light. There was a very general desire on the part of the ratepayers for the introduction of the electric light, and the district in question would be lighted at a cost of not more than 4d. in the pound to the rates. The City was well lighted as it was, but compared with Paris and other Continental cities, where the gas light was in use, it was very badly illuminated. The committee had earnestly considered the question of lighting the whole of the City, but the cost of lighting the small by-streets made it very expensive. No doubt they were creating a monopoly, but unless some such concession was given they could not hope to have electric lighting in the City.

Mr. W. E. Pannell, though strongly in favour of having the electric light, urged that some string of forfeiture clause should be inserted in the contract. The Commission had had some experience in the matter, and had seen their agreements with other companies used entirely for Stock Exchange purposes, and without any consideration for the public interest. In the proposed agreement the Company were to be at liberty to continue the private lighting, although they may not be able to continue the lighting of the public lamps which it was admitted, would be supplied at a loss to the Company. Thus the Company, immediately they obtained the monopoly, would have the power of repudiating their agreement to supply the public lamps. Again the Company would not be bound to supply all who desired to have the light, and they could charge exactly what they liked. He moved that the report be referred back to the committee for further consideration as to the points he had mentioned.

Mr. C. T. Harris advised the Commission to exercise particular caution in the matter.

Mr. F. Orson remarked that if the chairman of the committee would consent to insert a forfeiture clause the Commission were practically agreed upon the report.

Mr. J. C. Bell, in reply, said they were bound to take some risk in the matter. He thought the fact that the Company would have to expose a large sum in laying down their plant should be a sufficient guarantee. No company would consent to the insertion of a money penalty forfeiture clause. Electric lighting had been sufficiently handicapped by Act of Parliament without the Commission throwing obstacles in the way.

The amendment of Mr. Pannell was carried by 20 votes to 8, and the report was referred back for reconsideration.

CITY NOTES.

Financial.—Owing to the success of the Anglo-Cables in their legal proceedings against the French Cable Company a rise in the shares has taken place during the week. A rise also is recorded in Anglo-Brush shares.

New Company.—The Platinum Plating Company (Limited) is a new company with a capital of £60,000, in 59,100 ordinary shares of £1 each, and 900 founders' shares. The present issue is of 59,100 ordinary shares. The objects of the company are stated to be to

acquire patent rights for, and to introduce throughout the United Kingdom of Great Britain and Ireland, the Empire of India and the British Colonies (Canada excepted), a discovery believed to be of great value, whereby platinum can be successfully deposited upon all descriptions of articles made of brass, copper, steel, or other metals, with a brilliancy of surface and colour hitherto unattained.

Brazilian Submarine Telegraph Company.—The traffic receipts of the Brazilian Submarine Telegraph Company for the past week amounted to £4,491, and those of the Western and Brazilian Company, after deducting the "fifth" of the gross receipts payable to the London Platino Brazilian, were £3,613.

NOTES.

Iron-clad Dynamos.—Mr. J. Wenstrom claims priority in the design of these dynamos.

Halifax. The Halifax Football Club has had its ground furnished with the electric light. The field is surrounded by arc lights suspended from high masts.

Japan. The electric light is becoming increasingly popular in Japan. A number of lights have now been fitted up at Sakamotocho and Kyabacho, Tokio.

Appointment.—M. A. Bandsept, of Brussels, has been appointed engineer-in-chief for the electrical and lighting departments at the Grand Concours Exhibition during the present year.

Time Regulation.—At a recent meeting of the *Académie des Sciences* M. Cornu read a description of an improved arrangement for synchronising clocks and transmitting time indications.

Society of Arts. Two lectures will be delivered by Prof. O. J. Lodge, D.Sc., F.R.S., on the "Protection of Buildings from Lightning," on Saturday afternoons, March 10th and 17th, at three o'clock.

The New Telephone.—Like the apparatus of other companies, the New Telephone is being employed in large works instead of speaking tubes. Mr. T. H. P. Dennis has taken the agency for Chelmsford.

Dundee.—A sum of nearly £1,000 has been subscribed for the proposed Victoria Art Gallery. The estimated cost is between £9,000 and £10,000, and a further sum to carry out the intention to illuminate the rooms with the electric light.

The "Himalaya."—Readers of the daily papers will know that this transport in going out of harbour fouled the mooring chains of a buoy with her propeller. A staff of divers, assisted by the electric light, enabled the vessel to be cleared.

Secondary instead of Primary Batteries. The Exchange Telegraph Company have replaced 2,000 primary batteries by 210 "E.P.S." accumulators. It is expected that this successful experiment will lead to a greater use of storage batteries for telegraphic and telephonic work.

Electro-Harmonic Society.—The next smoking concert of this society will be held at the St. James's Hall Restaurant, Jan. 27, at 8 o'clock. A good programme has been arranged by the musical directors Messrs. Gatehouse and Thompson in which the following artistes will take part:—Messrs. Walter Coward, Arthur Thompson, James Kift, Musgrove Tufnail, C. Hann, and Alfred Izard.

A Portable Cell.—Mr. Cox has suggested the use of gelatine instead of a liquid in a cell which has to be carried about. To the prepared gelatine, sal ammoniac or other salt used is uniformly mixed with the gelatine. When the mass is thus prepared a little bisulphate of mercury is added, which improves the electrolyte and keeps the zinc amalgamated, and the whole preparation is then packed around the electrodes.

Tar or Coal.—Some of our contemporaries are carried away by any new suggestion, and the design of a new thermo-engine to burn tar is supposed to be the thin wedge that will soon oust all steam-engines burning coal from the market. Have those who foretell these changes asked

themselves the question, how the price of tar, creosote, etc., would compare with coal if the demand for tar approached anything like the proportions of that for coal?

Telephone Trunk Lines. The construction of the telephone between Dundee and Kirkcaldy via Tayport was completed last week, and as Kirkcaldy is already connected with Edinburgh and Glasgow, telephone communication from Dundee is now greatly extended. After the connection had been made, the operators at Dundee exchanged the compliments of the season with the officials in Kirkcaldy and Stirling, and afterwards with those in the Glasgow and Edinburgh offices.

Electricity in the Classics.—It is well known that many people are easily susceptible of a static charge of electricity, and it may be a phenomenon of this kind that Virgil refers to when he mentions the harmless flame emitted by the hair of Ascanius—

"Ecce levis summo de vertice visus tui
Fudere lumen apex, tactoque innoxia molli
Lambere flamma comas, et circum tempora pasci
Nos pavidi trepidare metu, erimenque flagrantem
Excutere, et sanctos restinguere fontibus ignos."

Telephonic Millenium.—The *Western Morning News* seems anxious to arrive at the epoch when a telephonic talk, like a letter, will be carried for a penny. Our contemporary kindly informs us the time is fast coming, "but probably it will not dawn until all the telephonic patents have become public property." The happy time to come when the "telologue" is to be one penny depends upon other questions than who possesses the patents. Time and space have to be considered—how long and how far for a penny?

Canada. The Canadian railways are experimenting with the electric light. It is singular that, with one or two exceptions, so little is done by our railway companies to improve the lighting of their carriages. Local trains are mostly patronised by business men who live away from the factory or warehouse. Many of these business men would be glad of a light that would enable them to comfortably read the paper in the evening as they returned from business. Time is of so great importance nowadays, that many could usefully employ the time spent in the railway carriage if the light given was sufficient, instead of being only just enough to make darkness visible.

Journal of the Society.—The current number of the *Journal* contains papers on "Deep-sea Soundings in Connection with Submarine Telegraphy," by W. E. Stallibrass, on "Some Instruments for the Measurement of Electromotive Force and Electrical Power," by Prof. J. A. Fleming and W. C. H. Gunningham; and one on "Portable Voltmeters for Measuring Alternating Potential Differences," by Profs. Ayrton and Perry, besides an original communication by Mr. A. E. Kennelly on the "Superiority of the Earth-overlap Method Localising Small Faults in Cables;" and a number of abstracts and titles of electrical papers. It will be seen that the number contains a variety of interesting matter.

Electrical Dissipation of Smoke.—It is said that the discovery by Professor Lodge of the curious effect of discharges of static electricity upon dust and vapour has been taken advantage of by Mr. J. G. Lorrain in the construction of an apparatus for the dissipation of smoke resulting from the discharge of ordnance. Mr. Lorrain proposed to employ an electrostatic generator, such as Wimshurst's, in communication with appropriate con-

ductors arranged around the mouth of the gun, and as a conductor he prefers a light wire lattice provided with points. It is possible that such a device may be successful, but trials on a full working scale will be necessary before any definite opinion can be expressed.

Dublin. It is well known that the Dublin Corporation are considering the question of utilising the water-power in their possession at Island Bridge for an experiment in electric lighting. Island Bridge is about two miles from the streets it is proposed to light, and the water-power available is estimated at 50 h.p., which is expected to be sufficient to obtain a current for 45 arc lamps, each of 2,000 c.p. nominal. Estimates were advertised for last November, the specification having been prepared by the city engineer, but only three tenders were received in response, and neither of these has been deemed satisfactory. The municipal authority has therefore ordered that further estimates be advertised for, and it is expected the advertisements will appear immediately.

Alternate Currents. There is a growing disposition to use alternating currents with transformers, and if the Thomson-Houston system in this direction is as successful as in arc lighting their competitors must look to their laurels and to their pockets. According to American advices the Thomson-Houston Company is doing a large business with its alternating system of incandescent electric lighting. The demand is so good and constant that a stock of apparatus for the distribution of energy for lighting by alternating current, including dynamos, of capacity from 250 to 1,000 lights, the necessary transformers, potential and current indicators, together with a complete system of feeder boxes, junction switches, and all other devices necessary is kept to supply urgent orders.

Electrical Symbols. In *l'Electicien* of the 7th inst. M. E. Hospitalier states that he has been unsuccessful in his endeavours to introduce, through the intermediary of the *Société Internationale des Electriciens*, a universal system of notation and symbols in electrical science, one important result of which would be a great saving of space and time by avoiding the necessity for defining the symbols for the values most frequently referred to in this science. He gives, however, the notation, abbreviations, and symbols, extending over nearly five pages, which will henceforth be adopted in the paper under his editorship. We observe that the symbol for work and energy is W, and in many other cases the symbols adopted are those in common use in this country. The symbol for current, however, is I, instead of C, which is now almost always adopted here.

The Tudor Accumulator. This form of secondary battery, which is somewhat analogous to that of M. Somzée, has been tested with satisfactory results in Germany and Luxembourg. The principle of its construction is said to be the adoption of central supports of which the section is a cross, thus obtaining great rigidity and facilitating the application and retention of the active material. But the point of greatest novelty in the manufacture of the battery is the "forming" of the lead supports by the passage during several days of currents alternately in opposite directions, according to the method of Gaston Plante. Thus a *liaison* is obtained between the metallic conductor and the layer of active material subsequently applied, and it seems probable that the connection so established would be more perfect than that due to the comparatively very thin layer of peroxide and spongy lead formed on the surface of the supports in the ordinary process of charging.

A Long Streak of Electricity. The Jenney Electric Company yesterday received a telegraphic proposition from Auckland, New Zealand, which contained seventy words, and cost the sender \$2.71 for each word. It is interesting to note the line of travel followed by this message in reaching its destination. The first repeating station was at Wellington, thence to Sydney, Australia, thence across the country to Palmerston, from there *via* cable to Saigon, Siam, then to Calcutta, thence across Hindustan to Bombay, from there under the Arabian Sea to Mocha, thence up the Red Sea to Mount Sinai, thence across Egypt to Alexandria, then to Palermo; from there under the Mediterranean to Gibraltar, thence to Lisbon, London, Queenstown, New York, and Indianapolis. To fill the order, Brainard Ransom says, would test the capacity of their works for one month, and the reply, "Impossible, factory overloaded," was reluctantly sent. *Indianapolis Daily Journal*.

Output of Bell Instruments. The output of telephones by the Bell Company for the month and year ended December 20, is appended with comparisons.

Month Dec. 20.	1887.	1886.	Increase.
Gross output	3,486	3,946	*460
Returned	2,094	1,686	408
Net output	1,392	2,260	*868
Since Dec. 20.	1886-87	1885-86	
Gross output	52,156	42,305	9,850
Returned	26,789	19,921	6,865
Net output...	25,367	22,382	2,985

*Decrease.

This makes the number of telephone instruments in the hands of licensees December 20th, 1887, about 378,885, against 353,518 in 1886, 330,040 in 1885, 325,674 in 1884, 298,580 in 1883, and 237,728 in 1882. The gain in 1886 over 1885 was 23,478.

Blackfriars-road. Upon the recommendation of the Roads Committee of the St. George's Vestry, it was resolved "that the application of the Anglo-Brush Co., for permission to lay electrical conductors under the footway on the west side of the Blackfriars road, according to plans to be approved by the vestry, and offering to supply the electric light to the inhabitants of the Blackfriars road upon the same terms as the current is supplied elsewhere by the company, be granted upon condition that the company enter into an agreement to be prepared by the vestry's solicitor, all costs and charges of such agreement to be paid by the company; that before breaking up the pavement notice be given to the vestry, and the reinstating of the pavement be done to the satisfaction of the vestry's surveyor, that a nominal rent of five shillings per annum be paid to the vestry by the said company, and that all expenses of, and incident to, the carrying out of the above from time to time be paid by the said company, and the contract be terminable by six months' notice on either side."

Electric Lighting at York. Messrs. Rowtree, Hills and Co., of York, have recently adopted the electric light in their shops. The installation, which has been carried out by Messrs. J. H. Holmes and Co., Newcastle-upon-Tyne, consists of one of their No. 8 "Castle" dynamos (compound wound) giving 70 amperes 60 volts, at a speed of 1,000 revolutions, driven by a 6 horse-power "Stockport" gas engine. The shops are lighted by 9 of Holmes' "Castle" arc lamps, which received a silver medal, the highest award at the Newcastle Exhibition, and 5 small ones giving 100 candle power with a current of 5 amperes. The offices at the back of the premises are lighted with 60-

volt Swan lamps. The arc lamps employed in this installation are of Messrs. Holmes and Co.'s new and improved type, including their recently patented arrangements for ensuring a definite feed and thus regulating the lamps with great certainty. The creamery is elaborately panelled with decorated tiles, and the small arcs in this department give a charming effect.

Alloys.—Mr. Warren recommends an electrolytic method for the preparation of certain alloys such as sulphur-bronze, silicides, &c. The metal and substance containing alloying material are placed in a deep conical crucible, through the bottom of which passes a rod of graphite, extending about one inch within the crucible and protected on the outside by an iron tube. The metal is melted and the graphite is put in connection with the negative pole, whilst the molten substance on the surface is connected with the positive pole of a battery of two large ferric chloride cells. In this manner silicon-copper and silicon-iron are easily prepared from potassium silicofluoride and the respective metal; the salt being taken in sufficient quantity to form a molten layer two inches deep. By some slight variation in the details, phosphor-bronzes can be produced; moreover, native cryolite can be decomposed in contact with metallic zinc, and on subsequently volatilising the zinc, pure aluminium is obtained. Magnesium, barium, strontium, and calcium have not yielded satisfactory alloys as yet.

Copper.—Now that copper, which is so largely used in electrical work, has reached its present price, inquiry has naturally arisen as to the extent to which production can and will be increased. Our contemporary, *Iron Age*, a leading authority on these questions, taking a careful survey of the situation, remarks: "On the whole, production of copper is not so elastic as many might be inclined to believe. The product will certainly increase quite rapidly, but the amounts thrown upon the market by mines which have been idle for years will be small for six months to come. We look for the principal increase from those producers who have found 10 to 12 cents above the cost at which they could deliver the metal into consumers' hands." In other words, the return to normal values will be slow. We are a little interested to see what effect the higher price of copper is going to have in causing resort, where possible, to other metals that are cheaper, but are of less conductivity. The situation is certainly one that gives emphasis to the claims of superior economy made for the alternating system, and will encourage generally the use of higher potentials.—*Electrical World*.

The Ampere-Standard (Ampere-Etalon) of M. Pellat.—This instrument is a balance-electro-dynamometer similar to the absolute dynamometer submitted to the *Société Française de Physique* by the same savant about a year ago, but of smaller dimensions. It measures the intensity of a current by the number (f) of grams which, when placed in the scale-pan of the instrument, will balance the electro-dynamic couple produced by this current. The formula employed is

$$C = k \sqrt{f},$$

in which k is a constant for a given locality, which is independent even of temperature, and which, for any other locality, varies as the square root of the intensity of gravitation. This constant is determined once for all by a comparison with an absolute electro-dynamometer. The sensibility of the balance is such that it will, with the aid of the microscope, indicate a difference of $\frac{1}{10}$ milligram.

Thus, since a current of .5 ampere is balanced by 1500 milligrams, f may be determined to $\frac{1}{15000}$; and, since C varies as \sqrt{f} , the limit of error does not exceed $\frac{1}{150000}$.

The apparatus allows of the calibration, by derivation or otherwise, of all instruments intended for the measurement of currents in practice.

Meteorological Society.—At the annual general meeting of this society, held on Wednesday at the Institution of Civil Engineers, 25, Great George-street, Westminster, Mr. W. Ellis, F.R.A.S., president, in the chair, the report of the council showed that the society was in a satisfactory condition, the number of Fellows being 522. Mr. Ellis, in his presidential address, reviewed briefly the work and position of the society. He remarked that, although they were unable to carry out expensive original or experimental work, they could act with great advantage in inciting volunteer workers throughout the country to united action. One recent example of this was the ready response to the request of the society for photographs of lightning. An excellent collection of photographs had been obtained and would shortly be exhibited. Arrangements were also being made for the more systematic observations of thunderstorms. Referring to the question of sympathetic relation between sun spots and magnetism and meteorology, he thought that any complete treatment of the question in its meteorological aspect seemed to require that it should be dealt with in a much more comprehensive manner than before. For this purpose observations more completely covering the surface of the globe might be necessary.

Electric Lighting at Lucerne.—The Schweizerhof Hotel is now entirely and splendidly illuminated by electricity. Incandescent lamps have been fixed in the passages, cellars, kitchens, and bed rooms, even to the garrets situated on the fifth floor. At any hour of the day or night these can be brought into operation merely by pressing a button. Both the arc and the incandescent lamps act with the most perfect regularity, never becoming extinguished or varying in the intensity of the light. Within the interior of the hotel there are no machines nor space occupied, nor staff to superintend the lights. The electrical supply enters the building by the wires from the works of Gebrüder, Troller and Co., situated at Dorenbourg, about seven kilometers west of Lucerne. These works supply not only the hotel installation, but many others, the total number being 2,000 incandescent and 15 arc lamps. The installation was carried out by Ganz and Co., of Pesth, on the Zipernowski system. The turbine, made at the works of Bell and Co., at Kriens, is of 125 horse-power. The hydraulic power itself is nearly 250, and by increasing the fall from 7 to 18 metres might be increased to 450 horse-power. In winter when, by reason of hard frost, the hydraulic power cannot be utilised, the turbine is replaced by a steam engine of 150 horse-power. The superintending staff is composed of five workmen, of whom three are at work in the day and two in the night time.

Irish's Electric Railway System.—In attempting to overcome the disadvantages of the overhead and conduit systems of electrical transmission to the cars of street railways, a Cleveland gentleman has conceived the idea of a conduit that will need no drainage, will exclude all moisture and remain closed and sealed at all times, yet at the same time it will admit of an electrical connection being made by the proper mechanism. The arrangement is to lay two

channels in the pavement, the sides of which are just below the street grade. Each of these channels carries one of the conducting wires from the dynamo. The conduit or channel is made of soft rubber, and affords the only insulation that is supplied to the wires. Attached to the conduit along its upper surfaces there are short rail pieces, which rest on shoulders on the top, and which, when in their normal position, are flush with the level of the street. Inside of the tube and corresponding to the rail pieces there are short strips of contact pieces, which are insulated from the rail strips except where they are firmly united by screws. The action of the device is as follows:—Underneath the car there are contact wheels with a concave rim which run upon the rails of the conductor. They are pressed down by a spring of sufficient tension to overcome the resistance of the rubber conduit. The elasticity of this rubber is all that is depended upon to hold the contact pieces away from the wires. As the rails are independent of each other, they can be pressed down upon the wires, one after another, as the car passes. It is this contact that furnishes the electricity for the propulsion of the car. The stream is continuous, as one of the sections is not freed from the contact until the next one has been pressed down. The conductors at the bottom of the tube are coupled together by means of a variable expansion joint, which will allow of expansion and contraction of the sections composing the conductors, under varying temperatures. The motor, designed by the same inventor, is very flat, and is intended for use under the body of the car.

Electric Outposts. Some information was recently published in the *Pittsburgh Gazette* respecting a discovery by Daniel Drawbaugh, whose right to priority in the invention of the telephone will soon be decided upon by the Supreme Court of the United States. He has almost completed an insignificant little piece of electrical mechanism that may have an important bearing on the warfare of the future. It consists of what Mr. Drawbaugh calls a microphone and registering dial. The microphone is placed in a hollow iron tube, which is hermetically sealed. When it is to be used on land the microphone is attached to an iron screw with a very wide thread, by means of which it is sunk firmly into the earth. An insulated wire connects with a galvanic battery and registering dial, which may be placed miles away. The registering dial is surmounted by a needle that works from zero point. Underneath the dial, in the small circular brass box that it covers, is another needle in the form of a working beam like those seen on side-wheel steamboats. When the vibrations of sound, either by the medium of earth, water, or air waves, affect the microphone, the needle beneath the dial dips. The dipping puts one end of the steel into a pot of mercury, and a new local current of electricity is started, which moves the needle on the face of the dial and serves to give the alarm. The practical working of the instrument is intended to assist the picket lines of an army. It is hoped that a commanding officer may sit in his tent, supplied with a registering dial, and be kept informed of the approach of a large body of troops from any direction by a proper distribution of the stakes containing the hermetically sealed microphones, a dozen of which may be used as the situation demands. The instant the air or earth vibrations caused by the tramp of feet or the sound of voices affect the microphone, that instant the effect is shown on the face of the dial by the turning of the needle from the zero point. It may not be known to Mr. Drawbaugh, it may not be known to many of our contemporaries, that the microphone

has long been used to record earth vibrations. The indefatigable young men who made a strong attempt to move the centre of the scientific world from Europe to Japan, buried microphones in all directions to record seismic vibrations, and found that other vibrations were recorded.

An Electric Chess Recorder. A very ingenious and novel electric machine for the automatic registration of the moves made during a game of chess has been invented by Dr. Wursterburger, of Zurich, and is now on view at the office of Messrs. Woodhouse and Rawson. The invention consists of two parts, the chess board and the recording machine. The board is, to all intents and purposes, an ordinary chess board, the men fitting by means of feet into circular holes made in the centre of each square. The under side of the board is fitted with wires connecting with the recording machines, and the insertion of a piece in any particular hole makes the contact complete, and starts the current, which is broken on a piece being lifted. The recorder consists of a motor driving a printing wheel, to which is attached a series of small brushes acting on a commutator, to a section of which each square of the board is electrically connected. The printing mechanism is acted on by an electric magnet, which is brought into play by the brush passing over the particular section of the commutator to which the squares upon which the piece is moved belong. A very ingenious portion of the invention is the method by which the difference in the marking of the black and white moves is recorded. This is accomplished by means of a switch coupled up to the wires connecting the black pieces, which when brought into play throws the two lines of type further apart, showing the difference between the white and black moves at a glance. The recorded moves appear on an ordinary telegraph tape, and the whole is perfectly automatic in its action. The apparatus exhibited the only one yet made is, as might be expected, rather an example of inventive ingenuity than a practical instrument, the cost of the machine being sufficiently high to prevent its coming into general use. We understand that the instrument has cost £80 to make, but its working is sufficient to show the feasibility of the idea, and we shall be glad to hear that its capabilities are to be tested at an important match or tournament.

Carlisle (Maryport).—Last week the Mayor of Carlisle publicly opened the National Telephone Company's trunk line between Carlisle and Maryport, which now completes telephonic connection between the county town and Whitehaven. From Maryport to Workington there are two trunk wires, and from the latter place to Whitehaven three. The new line from Carlisle has been anticipated for some time, but it was only within the last two months that its actual construction was undertaken, and finished under the superintendence of Mr. F. F. Bennett, Manager of the National Telephone Company in Cumberland, assisted by Mr. Jamieson, district manager, Carlisle. By its completion the whole of the West Cumberland system, including Maryport, Workington, Whitehaven, Cleator Moor, Frizington, Cockermouth, and Parton are brought into direct communication with the county town. The new line runs through Wigton, Aspatria, and on to Maryport. It is now three years since the telephone was introduced into the west of Cumberland, and since then between 400 and 500 miles of wire have been opened out. In the two years that the telephone has been in existence in Carlisle there has been 61 miles of wire erected. In the west of the county the subscribers number

about 250, and in Carlisle 57. The longest distance over which a person can speak on the wires is from Dalton to Egremont, both of which are loop wires, the distance being 54 miles. Subscribers now will be able to hold converse from their places of business with each other from either end of the county, and the outside public can also use the call offices and hold a conversation of three or four minutes duration on payment of a small fee. At the opening proceedings, Mr. Bennett, in reply to the toast of the Company, said that although at first they did not meet with success, recently the system had been increasing, although it was still far behind other parts of the kingdom. In ten towns taken from England, Scotland, and Ireland, which he named, the average all over was one subscriber to every 358 of the population. In Whitehaven they had one subscriber to every 285 of the population, Workington one to 421, Carlisle one to 600, Maryport one to 810, or taking the average of the four towns one to every 529 of the population. He claimed the telephone to be the cheapest mode extant for communication, and pointed out the advantages it offered for the detection of crime where police offices were connected by wire; and also what an immense boon it would be to the shipping interest on the Cumberland coast if the lighthouses, harbour offices, and coastguard stations were all joined together by wire.

Telegraphists' School of Science.—The twelfth annual distribution of prizes in connection with the above took place last Friday evening in the Postmaster-General's deputation-room. Considerable interest was manifested in the proceedings, which, in the unavoidable absence of the Postmaster-General, were presided over by Mr. C. H. Fischer (controller), who was supported by Mr. C. H. B. Patey, C.B. (secretary to the Post Office), Mr. W. H. Preece, F.R.S., and leading members of the department. For the City and Guilds Institute examination, the first prize in the United Kingdom for telegraphy, a silver medal and £5, was awarded to Mr. Frank Tandy, with a first-class honours certificate. Other successful students were: First-class honours, Mr. J. Bailey and Mr. F. S. Parkinson; second-class honours, Mr. C. W. Winn. Ordinary certificates: First-class, Mr. W. J. Callow, Mr. A. G. Cardrey, Mr. A. E. Chapman, Mr. H. E. Cheel, Mr. C. H. Fleetwood, Mr. E. Harris, and Mr. J. McPherson; second class, Mr. H. Maguire and Mr. R. J. Talbot. For electrical instrument-making—honours certificate, second class, Mr. G. F. Mansbridge. For the Science and Art Department examination certificates: Mathematics (advanced) Mr. A. Brooker. Elementary—first class, Mr. F. Tandy; second class, Mr. J. Bailey, Mr. W. J. Callow, and Mr. H. Maguire. Magnetism and Electricity (advanced) first class and Queen's prizes, Mr. James Bailey and Mr. W. H. Cheel; advanced second, Mr. A. E. Chapman, Mr. C. H. Fleetwood, Mr. F. S. Parkinson, and Mr. C. W. Winn. The leading local prizes were to Mr. J. Bailey and Mr. F. S. Parkinson, for passing with first-class honours in telegraphy. First class, ordinary, or telegraphy: Mr. W. J. Callow, Mr. A. G. Cardrey, Mr. A. E. Chapman, Mr. H. A. Cheel, Mr. C. H. Fleetwood, Mr. E. Harris, and Mr. J. McPherson, and Mr. F. Tandy for first-class in mathematics. The aggregate prizes were—the Controller's (first) to Mr. F. Tandy, and the Sub-Controller's (second) to Mr. James Bailey; these were accompanied by testimonials. The Engineering Superintendent's (third) was gained by Mr. W. J. Callow. Mr. Patey assured the meeting that the department would do all in its power to insure the continued prosperity

of the classes, which had already been so marked a success. Mr. Preece impressed upon his hearers the practical advantages that would accrue from their following up their studies. A merited tribute of praise was accorded to Mr. W. Slingo, who is the teacher of the classes. A vote of thanks to the chairman and Mr. Preece concluded a very successful meeting.

Lectures on Electric Lighting.—We are glad to see the diffusion of more correct information about electric lighting among the masses by means of popular lectures. Mr. C. J. Snelus, F.R.S., has delivered such a lecture at Workington—that is in the midst of a district where trustworthy facts about electric lighting are calculated to bear good fruit, and lead to an increased use of the illuminant. We shall not follow Mr. Snelus through the whole of his lecture, but give the gist of his remarks on incandescent lighting. He said: "Light may be produced by passing a current through a conductor which offers great resistance to its passage, as, for instance, a fine wire or thread of carbon. This is the basis of incandescent lighting. It was shown that when the current was passed through a fine steel wire the wire became red, then white hot, and finally melted. When passed through a thread of carbon the thread became white hot, and then burned. After many experiments, electricians found that the thread of carbon was the only successful medium for producing a light, but to prevent it burning away it is necessary to enclose it in a glass globe, from which the air is subsequently exhausted. In making glow or incandescent lamps, the carbon thread has first to be formed. Swan uses a cotton thread, which he steeps in dilute acid, then carbonised at a high heat embedded in charcoal. Edison uses thin strips of bamboo, which he carbonises in the same way. The carbon threads are then joined at each end to small platinum wires, formed into a loop, which is placed in a small glass bulb, and the platinum ends sealed into the glass by the blow pipe. The air is then exhausted from the bulb by a Sprengel pump, and the bulb sealed up by the blow pipe. So perfect is the vacuum in these lamps that only one particle per 4,000,000 is left in the bulb. As an illustration of the freedom of motion left to the remaining particles in an exhausted bulb, the lecturer passed the current from an induction coil through a Crookes vacuum tube, in which a light set of vanes, or windmill, was delicately poised. The few particles of air left in the bulb were repelled from the pole enclosed in the bulb, striking the vanes with great velocity, and causing the mill to spin, while the globe was filled with a beautiful purple light. To show the perfection of the vacuum in an ordinary lamp, the lecturer broke the point of one under some coloured water when the water immediately rushed in and filled the globe. The mode of fixing the lamps was then explained, and recent electric installations referred to. Mr. Snelus concluded by remarking that probably the finest installation of incandescence lighting was that at the Newcastle Exhibition, where lamps of 1,000 candle-power were shown, and large numbers of 500 and 800 candle-power, by Messrs. Clarke, Chapman, and Parsons, of Gateshead, under the name of the "Sunbeam" lamp. Two of such lamps of 200 candle power were handed round for examination, and the lecturer said that he considered these lamps constituted one of the greatest advances that had been made in electric lighting, and if they really were as durable as they were said to be, he thought they would rapidly displace the arc light, and immensely cheapen the cost of lighting up large spaces.

CONSTANT SPEED MOTORS.

BY J. SWINBURNE.

Since the beginning of 1886, when Mr. Mordey first brought before the electrical world the theory that the principles of design are the same in a motor as in a dynamo, the truth of his views has been gradually acknowledged. In his article in the *Philosophical Magazine* Mr. Mordey makes some remarks, however, which are now known to be incorrect, and which he found to be so almost immediately the article was published. One of these was in reference to the supposed less efficiency of the motor, and another to the supposed analogy between constant E.M.F. dynamos and constant speed motors.

The idea is nearly universal now that a constant speed motor should be a sort of differentially wound machine. To get clear views, the action of a dynamo and motor must be considered, so that we may know what is required to make a constant speed motor.

Take the case of a separately excited dynamo which gives say 100 volts on the terminals with no current. Suppose, to fix the ideas, that the armature resistance is $\frac{1}{10}$ ohm, and the full current 100 amperes. At the full load of 100 amperes, suppose it is found that the machine gives 80 volts. As the armature resistance is $\frac{1}{10}$ ohm, 10 volts must be lost over it; so the armature E.M.F., which may be called E in accordance with Prof. Thompson's notation, is 90 volts.

The total armature induction is therefore lessened 10 per cent. The diagram has been used by the writer to explain this. Suppose AB is the diameter of commutation, then

the wires with currents going one way on the outside of the armature may be represented by black dots, and those with currents going the other way by little circles. The armature may be divided by two vertical lines, CD and EF . The wires between these lines may then be considered to form a coil which opposes the field magnet coils, thus lessening the armature induction. The other wires do not lessen or increase the armature induction, so their action need not be discussed here. To make the machine give 100 terminal volts the action of the field coils must be increased enough not only to overcome the opposition due to the wires between CD and EF , but to increase the total armature induction enough to make $E = 110$ volts. In a compound machine the series coils do this.

By induction, of course, magnetic induction is meant, not the induction of currents which is due to the change of magnetic induction through a closed conducting circuit.

Now, suppose the machine is wanted to run as a motor. We may either move the brushes to E and D and allow the machine to run the same way, or the machine may be run the opposite way, the brushes remaining at C and F , being merely turned, so that the commutator does not run against them and turn their ends up. In either case the armature wires between CD and EF oppose the induction. I have therefore for some time called this action the back induction, and the action of the other wires the cross induction.

Now as the dynamo at full load when fully excited gives 110 armature volts and 100 amperes at the normal speed, which we may suppose to be 1,000 revolutions per minute, we must expect the machine as a motor to have 110 armature volts. As the armature resistance is $\frac{1}{10}$ ohm, the terminal E.M.F. will be 120 volts.

Now, suppose the load removed so that the current falls practically to zero. As the back induction causes a diminution of the total armature induction corresponding to 10 volts, the back E.M.F. will rise to 120 at the same speed, so that the machine will still run at 1,000 revolutions. If, instead of being separately excited, the machine is shunt wound, of course, as the E.M.F. on it is constant, it still goes at the same speed. A shunt is, therefore, the proper machine to use as a constant speed motor. If the effect of the back induction is not equal to the loss by armature resistance, of course the speed is not constant. For instance, if the back induction lessened the total armature induction by an amount corresponding to 15 volts at full load, the machine would run slower at no load. Similarly if the effect of the back induction were small the motor would run faster at no load. Thus a machine which goes at constant speed with a high terminal E.M.F. and high speed will not go at constant low speed with a low terminal E.M.F. and the same field excitation, as the percentage loss by armature resistance is greater, while the percentage fall of armature E.M.F. by back induction is the same as before.

The back induction is, of course, dependent on the position of the brushes, and the position of the brushes is dependent on the design of the machine, so it is possible to design a machine which will, when simply shunt wound, run at constant speed with varying load.

Though the writer has for a long time understood the theory of the action of the armature currents, he has unfortunately been unable to publish it for commercial reasons, as it is a matter of very great importance in large machines. As Messrs. Crompton and Co. have always been very generous to their electricians in this matter, however, one cannot complain. The discussion of the design of motors with the position of non-sparking, arranged so that they run at constant speed, must therefore be omitted, and the winding of a given machine alone discussed. Suppose the back induction small the field will be too strong at full load, so some backward turns of series coils are needed on the field magnets to make up for their not being on the armature. These coils can never be so large as the series coils in a compound machine, because they only have to make up the difference of two effects instead of corresponding to their sum.

In a large high speed motor the effect of the back induction is more important than that of the armature resistance, so that series coils are needed to oppose the back induction as in a compound wound generator—that is, wound to assist the shunt coils.

It is then only in very small or slow speed machines that any backward main, to speak of, is needed; and the theory that a motor should be like a compound dynamo with its main reversed is wrong.

Differentially wound motors have another objection which seems to have been generally overlooked, namely, that they tend to start backwards. Of course, a motor with much back induction has the same tendency, if the brushes are put forward to begin with, but a motor should always be started with negative brush lead, so that the back induction is converted into forward induction. Of course it would spark if allowed to run like that. The writer had his attention drawn to the subject of shunt motors by Mr. Burton, who was one of Messrs. Crompton's pupils. In a discussion on the question of constant speed motors, he pointed out that as the object was to make a dynamo which would "compound down," and as a shunt dynamo compounded down, a shunt motor should run at approximately constant speed.

The electric motor has another property which is not known as well as it ought to be, namely, that it runs at more nearly constant speed than the dynamo which drives it. To take an imaginary simple case: suppose the field magnets and armature induction so small that the iron does not approach saturation, and suppose the effect of back induction and armature resistance neglected, if the external

E.M.F. falls to say 100 volts from 120, the back E.M.F. falls in the same proportion as the fields are weakened. The current then increases so that the power spent is the same as before, so that the speed does not vary. In practice a machine cannot be wound with its iron so slightly magnetised, as it would be unstable, moreover, the resistance of the armature would make the machine run slower to get the increased current. The back induction would increase as the current increased, and the brushes would need more lead as the field became weaker. On the whole the machine would run a little slower, but the speed would not fall anything like in proportion to the E.M.F. on the terminals. The same remarks apply to small differentially or large compound wound machines. The electric motor has, therefore, a property possessed by no others. Messrs. Crompton often use a shunt motor for driving dynamos when accurate tests are required and the engine speed varies.

As to the efficiency of motors the writer has already dealt with the subject to some extent elsewhere. There seems to be, however, a common impression that motors are not fully understood, and that there is a mysterious loss of power in them. Some imagine that both in dynamos and motors the armature resistance alters in some extraordinary way, others imagine that there is some source of back E.M.F. in the armature, due in some way to self induction, which lessens the output either with or without loss of power. The writer can only say that he has never observed any loss of power by increase of resistance, or by back E.M.F., and cannot see how such things could take place.

The efficiency of the motor is higher than that of the dynamo, not lower. This is due, not to the machine losing less power as a motor, but to the way efficiencies are reckoned. The same anomaly arises with interest and discount.

Take as a simple case a series shunt motor taking 120 volts and 100 amperes, and going at 1,000 revolutions per minute. The series winding is taken for simplicity, the power lost in it being assumed as equal to that lost in the shunt if it had been shunt wound. Suppose 10 volts lost in the armature, and 10 in the fields, and suppose 1,000 watts lost in conversion. These losses are very excessive, and are merely taken to make round numbers. As $r = 120$, and 20 volts are lost in internal resistance, the back E.M.F. $E = 100$. So the machine delivers 10,000 watts to its spindle, that is the product of 100 volts and 100 amperes. Of this, 1,000 watts is stray power, so 9,000 watts are given on the pulley. This is about 12½ h.p., but we need not go into h.p.s. As the motor takes $120 \times 100 = 12,000$ watts, its efficiency as a motor is 75 per cent.

Suppose the machine now run as a dynamo at the same speed and with the same current. The armature E.M.F. of course remains the same, $E = 100$, so $r = 80$. The output is therefore 80 volts and 100 amperes, or 8,000. The electrical power supplied to the circuit, including the armature and fields, is $100 \times 100 = 10,000$ watts. Taking the loss by stray power at 1,000 as before, the belt must supply 11,000 watts, to the pulley. The gross efficiency is therefore $\frac{8,000}{11,000}$ or 72½ per cent.

As already mentioned, the losses of power are much smaller in practice. A well designed large machine has an electrical efficiency of 95 per cent., and a gross efficiency of 80 per cent., or say that the efficiency of dynamo and motor together is nearly 80 per cent. With small machines it does not amount to from 70 to 80 per cent., including both machines and leads over short distances. Over long distances the chief loss is of course in the leads.

TELEPHONES INSTEAD OF SPEAKING TUBES.

We have recently recorded that the "Equitable" and "New" Telephone Companies have opened out a new field of operations, in that they are installing their instruments in lecture, warehouses, and hospitals in place of speaking tubes. The system adopted by the Equitable is herewith illustrated. The Swinton telephonic apparatus, Fig. 1, is employed. Here we see transmitter, receiver, call bell, and switch box. When not in use, the receiver hangs on a hook, and the call bell is in circuit. On removal the bell is cut out, and the telephone transmitter and receiver put in

circuit. The front of the switch box is fitted with plug holes, lettered with the names of the different stations comprised in the system. In connection with the terminals of the telephone is a flexible cord terminating in a small plug, which can readily be inserted in any one of the plug holes of the switch box.

For n telephones $n + 2$ wires are required, and these can be made up into a cable of very small diameter. For n speaking tube stations perfect communication can only be obtained with $\frac{n(n-1)}{2}$ separate tubes. Thus, to establish

direct communication between, say, 12 stations, 14 wires, making a cable of about ¼ in. in diameter, will do the work of 66 speaking tubes, occupying about 6 ft. of wall space, and for larger numbers of stations the saving is still more marked.

Fig. 2 shows diagrammatically the telephone instruments, switch boxes, connections, and battery for an installation of six stations, A, B, C, D, E, F, distributed

FIG. 1. Swinton Apparatus.

about a building. It will be seen that the left hand plug hole of each switch box is marked with the letter that denotes the individual station to which this switch box belongs. Z and C are the wires connecting the various switch boxes to the zinc and carbon terminals of the battery, and 1, 2, 3, 4, 5, 6 are the six line wires that are necessary to connect the various switch boxes together. The terminals of the boxes are numbered, and all bearing the same number are connected to the same wire. When the telephones are not in use, the receivers are all hung up on their respective switch hooks, and the plugs are inserted in the left hand plug holes of the several switch boxes. Thus the plug belonging to A is inserted in the hole marked A, that belonging to B in hole B, and so on, as shown in the illustration. Supposing A wishes to communicate with C, he has only to remove his receiver from its hook, remove his plug from the hole marked A of his switch box, and insert it in the hole marked C, to cause the call bell at C to ring, the ringing

of the bell being notified to A by a loud rattling noise in his telephone receiver, due to the current from the battery being rendered intermittent by the contact breaker of the bell at C. On C removing his receiver from its hook the noise ceases, and A knows that he can talk to C, and *vice versa*. When the conversation is completed, A must replace his plug in the A hole of his switch box, so that other stations may be able to call him up if required. In a similar manner any one of A, B, C, D, E, F can call up and carry on a conversation with any other, and A and B can talk together while C and D are doing the same, or any other combination can be effected.

power of calling up all the others, only these particular stations need have switch boxes containing the full number of plug holes, and be connected with the full complement of wires, the cost of the installation being thereby considerably reduced.

PRACTICAL ELECTRICAL UNITS.

BY W. B. ESSON.

(Continued from page 31.)

3. *Electro-motive Force; Difference of Potentials.*—Matter cannot be moved from rest without the application of force,

FIG. 2.—Connection for Six Stations.

The system is so arranged that if, say, B tries to call up A or C while the latter are conversing with one another, the absence of the rattling noise in his receiver on his attempting to call attention intimates to B that the line is engaged. This prevents interruptions of conversation and any possibility of confusion.

The above examples show the principles of the system when applied to six stations, but, of course, the switch boxes can be made with any number of plug holes for a system comprising any number of stations; and when it is convenient that only some of the stations should have the

and the assumption that electricity is an actual substance moving through conductors entails the farther conception of an electricity-moving or electro-motive force. The term *electro-motive force* is employed to convey the idea that potentiality of electric current has been established, but as force may be present producing mechanical stress without causing motion, so electro-motive force may exist, creating electric stress without producing a current. Though in a pipe leading down from a water tank and closed by a valve at its bottom end there is no current of water, the water-moving force is still present in the difference of water

pressure between the two ends of the pipe, and we have existing the potentiality of a current which can become an actuality when the valve is opened and the water allowed to pass. In similar manner when the armature of a magneto machine is spun round an electro motive force is created at its brushes, the magnitude of this force being measured by the difference of electric pressure produced or by the potentiality of current established. As long as the brushes remain unconnected externally no current will flow, but when joined by a conductor a current will at once flow from one brush to the other. As the flow of water in a pipe is due to the difference of pressure urging it from a higher to a lower level, so the flow of electricity from one point to another is due to the difference of electric pressure, and proceeds from a higher to a lower level, or from a place where the pressure is greater to where it is less. The difference in electric pressure is termed *Inference of Potentials*, and to the agency which establishes a difference of potentials the name electro-motive force, written shortly E.M.F., has been given. The unit difference of potentials is the Volt equal to about $\frac{1}{10}$ of the difference of potentials which can be set up by a Clark's standard cell. Since this cell produces a difference of potentials of 1.44 volt we say 1.44 volt is its E.M.F., and by making up the cell always in the same way we can rely upon the E.M.F. always having the same value at a fixed temperature. It will be understood that the E.M.F. expressed in volts is the total difference of potentials which the source of electricity is capable of producing. By suitable instruments the difference of potentials between any two points in the circuit through which a current is flowing can be accurately measured. The point at greater potential is termed positive to the point at lower potential termed negative, the direction of the current in a circuit being always from the higher to the lower level, or from positive to negative.

4. *Resistance.* The difference of potentials required to make a definite current flow between two points depends on the length, cross section, material, and temperature of the conductor. The difference of potentials required for example to send a current through a conductor of German silver will be about 13 times that required to send the current through an equal length and section of copper. There is determined between the difference of potentials and current in every circuit a ratio depending upon the kind of conductor employed and by this ratio is expressed the *Resistance* of the conductor. When the difference of potentials at the ends of a wire is doubled, the current flowing is also doubled, the resistance of the wire, so long as its physical conditions remain unchanged, being independent of the current flowing through it. The unit of resistance is termed the *Ohm*, and its value is such that through a conductor having a resistance of 1 ohm a current of 1 ampere will be caused to flow by a difference of potentials of 1 volt. A column of pure mercury 106 centimeters long by 1 square millimetre in section has at 0°C. a resistance of 1 ohm.

5. *Electrical Work.*—As in the case of water flowing in pipes we estimate the work done by the quantity of water passing multiplied into the difference of pressure, so in the case of electricity flowing in conductors the work done is calculated by the product of the quantity which passes and difference of potential. The coulomb has been defined as the unit of quantity, and the volt as the unit difference of potentials. The unit of electrical work is the product of these two, termed the *Joule*, and defined, therefore, as the work done by a coulomb in passing from one point to another, between which there is a difference of potential of one volt.

6. *Rate of Performing Work.* A statement of the work done in joules conveys no impression of the rate at which electrical work is performed, since the term joule does not embrace the idea of time. Generally we do not require to know the number of joules performed in an hour or day but desire to know the rate at which work is being performed at the moment of observation. The unit rate of performing work is one joule per second, this rate being expressed by the term *Watt*. Thus, when we say that the rate of doing work in a circuit is 50 watts we mean that 50 joules of work are performed in every second if the rate is uniform. It must be clearly understood by the reader that a watt is

not a quantity but simply a rate, and it will be seen that there exists between the joule and the watt, a relation very similar to that existing between the coulomb and the ampere. Yet about so simple a matter the greatest confusion has reigned in the past, and even now exists. We are continually hearing such meaningless expressions as "watts per second," and only recently was the watt defined by the British Association Committee as "the work done per second by the ampere passing between two points, between which the difference of potential is one volt." Here the joule and the watt are evidently blended in the direst confusion, though the definition was adopted on the motion of Mr. Preece, who is a great authority on the watt and all that pertains thereto. But the watt is no more work done than 50 miles per hour is a distance, or 10 per cent. a sum of money.

7. *Correlation of Electrical Units.* The relations these units bear to each other will have been understood from the definitions given, but for their fuller comprehension they are here briefly summarised. If Q is the number of coulombs which passes in t seconds and C the current in amperes, then the relation between quantity and current, assuming that the flow is uniform, is given by the expression

$$C = \frac{Q}{t}$$

If V is the difference of potentials in volts and R the resistance in ohms, the relation between the difference of potentials, resistance and current is given by the expressions

$$C = \frac{V}{R}, \quad V = CR, \quad \text{and} \quad R = \frac{V}{C}$$

these setting forth the conditions familiarly known as Ohm's law.

Calling J the work done in joules we have

$$J = QV$$

while the rate of doing work, provided it is uniform, in joules per second or watts, W , is expressed by

$$W = \frac{QV}{t}$$

Since the current in amperes $= \frac{Q}{t}$ by simple substitution we can write

$$W = CV, \quad \text{also} \quad = \frac{V^2}{R} \quad \text{and} \quad = C^2 R.$$

(To be continued.)

COMPOUND STEAM TURBINES.*

We shall begin by describing water turbines and some of their performances, together with the necessary conditions for economy in motors of this class. We shall then describe the compound steam turbine, and draw a parallel between it and the water turbine, showing by the help of the latter that the conditions for high economy are fulfilled in the compound steam turbine. We shall then give figures to show what the theoretical economy of the compound steam turbine should be, and then deal with the dynamo and its combination with the steam turbine. Water turbines have been for many years in extensive use in Europe and America, and have, after many experiments, been brought to a very high degree of perfection, as is shown by the numerous tests that have been made to ascertain their actual efficiency. Perhaps the most carefully arranged and the most exhaustive of these experiments are those made by Mr. James B. Francis on the Tremont turbine at Lowell, Massachusetts. The result showed that the horse-power indicated on the dynamometer attached to the shaft amounted in some cases to 79.3 per cent. of the total power of the water, whilst those made on another turbine of still more improved design gave an efficiency of 88 per cent. The theory of the turbine has been thoroughly dealt with and understood, and theoretical reasoning leads also to the conclusion that such a high efficiency in a turbine is quite possible provided that certain rules are adhered to in the design, and provided also that certain essential conditions as to the flow of water

* Paper read before the North-East Coast Institution of Engineers and Shipbuilders by the Hon. C. A. Parsons.

are provided for. All water turbines consist essentially of a set of fixed vanes, called guide blades, and a set of moving vanes called the wheel, the former guide the water towards the direction of motion of the latter. The important conditions for economical working being that the shape of the blades and the velocity of the wheel shall be so arranged that there shall be no shock or sudden change of the velocity of the water in passing from the guide blades to the moving blades, and also that as the velocity or energy of the water on leaving the wheel is lost it shall be reduced to the utmost extent by the formation of the blades. This leads us to inquire what has been found to be the best velocity of wheel to meet these conditions. In Mr. J. B. Francis' experiments, we find

Experiment.	Percent of Velocity of wheel, if Velocity due to head.	Efficiency
42	30	67
41	39	72
36	50	78
30	63	79.3

We have here then the speed which gives the maximum efficiency, and a measure of the diminution of efficiency corresponding to a reduced speed. The essential conditions for high efficiency are, as we have said, absence of shock and low residual velocity. These conditions, in the case of the water turbine, can be better obtained in the types called the outward or inward flow than in the parallel flow, for the large volume of water to be dealt with necessitates long blades of double curvature for the last mentioned type; these are objectionable, while it is more difficult to minimise the residual velocity of the water leaving the wheel. Principally these reasons have led to the more general adoption of the outward or inward flow types than of the parallel flow. After careful consideration, however, the parallel flow type seemed more suitable to the compound steam turbine, and has been accordingly adopted. Fig. 3 shows the arrangement of ninety complete turbines, forty-five lying on each side of the central steam inlet. The guide blades, R, are cut on the internal periphery of brass rings, which are afterwards cut in halves and held in the top and bottom halves of the cylinder by feathers; the moving blades, S, are cut on the periphery of brass rings, which are afterwards threaded and feathered on to the steel shaft, and retained there by the end rings, which form nuts screwed on to the spindle. The whole of this spindle, with its rings, rotate together in bearings (shown in enlarged section, Fig. 2). Steam entering at the pipe, O, flows all round the spindle and passes along right and left, first through the guide blades, R, by which it is thrown on to the moving blades, S, then back on to the next guide blades, and so on through the whole series on each hand, and escapes by the passages, P, at each end of the cylinder connected to the exhaust pipe at the back of cylinder. The bearings, Fig. 2, consist of a brass bush, on which is threaded an arrangement of washers, each successive washer alternately fitting to the bush and the block, while being alternately $\frac{1}{2}$ in. smaller than the block outside, and $\frac{1}{2}$ in. larger than the bush in the hole. One broad washer at the end holds the bearings central. These washers are pressed together by a spiral spring, N, and run in, and, by friction against each other, steady or damp any vibration in the spindle that may be set up by want of balance or other causes at the high rate of speed that is necessary for economical working. The bearings are oiled by a small screw propeller, I, attached to the shaft. The oil in the drain pipes, D and F, and the oil tank, B, lies at a lower level than the screw; but the suction of the fan, K, raises it up into the stand pipe, H, over and around the screw, which grips it, and circulates it along the pipes to the bearings. The course of the oil is as follows. The oil is forced by the propeller, I, and oiled the bearing, A (Fig. 1), the greater part passing along the pipe E to the end bearing C, some, after oiling the bearing C, drains back by the pipe F to the reservoir D, the remaining oil passes along through the armature spindle, oiled the bearings, B, and drains into the reservoir, D, from which the oil is again drawn along the pipe, G, into the stand pipe, H, by the suction of the fan K. The suction of the fan is also communicated to the diaphragm, L, and forms, with it and the spring, M, the principal part of the governor

which actuates the throttle valve, V. Fig. 3 is the electrical control governor, which will be further described in connection with the dynamo. It acts directly upon the controlling diaphragm, L, by admitting or exhausting a quantity of air, and thus exercises a controlling influence upon it. For small differences of pressure, the velocity of air or steam passing through orifices or short tubes is given by the same formula as that for water. The heads of pressure have to be calculated in each case in terms of the respective fluids, and for small differences of pressure the velocity of efflux is the same for the same head in all cases. This has been recognized as a fundamental principle, it has also been verified in some of the cases we are going to consider by actual measurements. We now proceed to consider the action and condition of the steam as it passes through the successive turbines, but, before doing so, it will be necessary to go into some calculation in order to form a correct basis to start from. The velocity of efflux of steam flowing from a vessel at 15.6 lb. per square inch absolute pressure through an orifice into one at 15 lb. absolute pressure is 396 ft. per second, the drop of pressure of 6 lb. corresponding to a diminution of volume of 1 per cent. in the opposite direction. We must now suppose that the turbines are so proportioned and the blades so diminished in size that each one nearer the steam inlet O has 1 per cent. less blade area or capacity than the preceding one all the way from each of the exhaust ends up to the centre. If we work this out we find that after forty-five turbines the pressure will be about 69 lb. above the pressure at the inlet. The steam will have followed some curve of temperature and volume very near the isotherm; but on the isothermal side of it, the velocity of flow will be slightly greater near the inlet, in consequence of the increased temperature. The steam enters from the steam pipe at 69 lb. pressure, it passes through the first turbine, consisting of a ring of guide blades and then a ring of moving blades, and falls 2.65 lb. in pressure, the velocity due to this fall in pressure is 386 ft. per second, its volume increases by 3.85 per cent. of its original volume, it passes the second turbine, falls 2.55 lbs., and again increases its volume in the same ratio, and so on till it reaches the last turbine, where its pressure is 15.6 lb. before entering, and 15 lb. on leaving it to flow into the exhaust pipe. The velocity due to the last drop is 366 ft. per second. The steam has therefore nearly the same velocity of flow for all the turbines; in other words, the error in assuming the velocity due to the head to be 376 ft. per second throughout does not exceed 3 per cent. The velocity of the wheels at 9,200 revolutions per minute is 150 ft. per second, or 39.9 per cent. of the mean velocity due to the head throughout the turbines. On comparing this ratio of velocity of wheel to velocity of flow with that of the Tremont water turbine, we find a corresponding efficiency of a little over 72 per cent. Hence in the compound turbine we are describing, the velocity of the blades is sufficient to secure a very high return of useful effect. We may therefore assume that if the blades be equally well shaped in the steam turbine as in the water turbine, and that the clearances be kept small and the steam be dry, then each turbine of the set will give an efficiency of at least 72.5 per cent. We say at least, because as each turbine discharges without check into the next, the residual energy after leaving the moving blades is not lost, as it is in the case of the water turbine we are considering (it amounts to from 3 to 5 per cent. of the energy), but continues into the next guide blades, and is wholly utilised there in assisting the flow. This unchecked flow from one turbine to another is a great advantage of the parallel flow type over other types where a number of turbines are compounded. It also minimises the skin friction, as nearly the whole of the moving part is covered with blades, and there is consequently no appreciable loss due to this cause. As each turbine of the set gives 72.5 per cent. efficiency, it follows that as the steam at all points expands gradually without shock, that the motor as a whole will give an efficiency of at least 72 per cent. of the total mechanical energy of the steam, or, in other words, over 72 per cent. of the power derived from using the steam in a perfect engine, without losses due to condensation, clearances, or friction, and such like. A perfect engine working with 90 lb. boiler pressure, and exhausting into the atmosphere,

would consume 20 5/16 lb. of steam per hour for each horse power; a motor giving 70 per cent. efficiency would therefore require 29 20/16 lb. of steam per horse power per hour. We have now gone sufficiently into the question to show clearly that in the compound steam turbine we have a motor whose theoretical efficiency is very high indeed. The fact that at each turbine of the set the temperature is constant, enables us to predict that there can only be a very minute loss arising from condensation. This has been conclusively verified by experiments with superheated steam, coupled also with the fact that "for small differences of pressure gases and vapours act like liquids in flowing through orifices and tubes, in virtue of the small differences of pressure, and that the velocity of flow is regulated by the fundamental formula $v = \sqrt{8gh}$. These three facts draw the analogy between the water turbine and the compound steam turbine for efficient working as close as it is possible to draw anything, and it does not seem too much to expect, in the larger sizes at any rate, an equally good efficiency.

The dynamo which forms the other portion of the electric generator, Fig. 1, is coupled to the motor spindle by a square tube coupling fitted on the square spindle ends. The armature is of the drum type, the body is built up of thin iron discs threaded on to the spindle and insulated from each other by tracing paper. This iron body is turned up, and grooves milled out to receive the conducting wires. For pressures of 60 to 80 volts, there are fifteen convolutions of wire, or thirty grooves. The wire starting at *b*, Fig. 4, is led a quarter of a turn spirally, *c*, round the cylindrical portion, *d*, then passing along a groove longitudinally is again led a quarter turn spirally, *e*, round the cylindrical portion, *f*, then through the end washer and back similarly a quarter turn, *g*, then led along the diametrically opposite groove, and, lastly, a little over a quarter turn, *h*, back to *a*, where it is coupled to the next convolution. The commutator is formed of rings of sections, each section is formed of short lengths; each length is dovetailed and interlocked between conical steel rings, the whole is insulated with asbestos, and when screwed up by the end nut forms with the steel brush a compact whole. There are fifteen sections in the commutator, and each coupling is connected to a section. The whole armature is bound externally, from end to end, with brass or piano-iron steel wire. The magnets are of soft cast iron and of the horseshoe type; they are shunt wound only. On the top of the magnet yoke is the electrical control governor, Fig. 3. It consists of one moving spindle on which are keyed a small soft iron bar, and also a double finger T. There is also a spiral spring X, attached at one end to the spindle, and at the other to an adjustable top head and clamping nut, Y. The double finger, T, covers or opens a hole in the face, U, communicating to the pipe, W, with the diaphragm, L. The action of the magnet yoke is to attract the needle towards the poles of the magnet, while by turning the head the spiral spring, X, is brought into tension to resist and balance this force, and can be set and adjusted to any degree of tension. The double finger, T, turns with the needle, and by more or less covering the small air inlet hole, U, it regulates the access of air to the regulating diaphragm, L. The second finger is for safety in case the brushes get thrown off, or the magnet circuit be broken, in which case the machine would otherwise gain a considerable increase of speed before the diaphragm would act. In these cases, however, the needle ceases to be attracted, falls back and the safety finger closes the air inlet hole. There is no resistance to the free movement of this regulator. A friction of a volt increase or decrease of potential produces a considerable movement of the finger, sufficient to govern the steam pressure, and in ordinary work it is found possible to maintain the potential within 1 volt of the standard at all loads within the capacity of the machine, excepting only a slight momentary variation when a large portion of the load is switched on or off.

The resistance of the armature from brush to brush is only 0.032 ohm, the resistance of the field magnets is 17.7 ohms, while the normal output of the dynamo is 200 amperes at 80 volts. This, excluding other losses, gives an efficiency of 97 per cent. The other losses are due to eddy currents throughout the armature, magnetic

retardation, and bearing friction. They have been carefully measured. By separately exciting the field magnets from another dynamo, and observing the increased steam pressure required to maintain the speed constant, the corresponding power was afterwards calculated in watts. The commercial efficiency of this dynamo, after allowing for all losses, is a little over 90 per cent. In the larger sizes it rises to 94 per cent. Assuming the compound steam turbine to give a return of 70 per cent. of the total mechanical energy of the steam, and the dynamo to convert 90 per cent. of this into electrical output, gives a resulting efficiency of 63 per cent. As steam at 90 lb. pressure above the atmosphere will, with a perfect non-condensing engine, give a horse power for every 20 5/16 lb. of steam consumed per hour, it follows that an electrical generator of 63 per cent. efficiency will consume 32 5/16 lb. of steam for every electrical horse power per hour. Again, with steam at 150 lb. pressure above the atmosphere, a generator of the same efficiency would consume only 22 2/16 lb. of steam per electrical horse power per hour.

The results we have so far actually obtained are a consumption of 52 lb. per hour of steam for each electrical horse power with a steam pressure of 90 lb. above the atmosphere. We, however, expect shortly to obtain results more nearly coinciding with those very high economies that theory has led us to believe possible with this system. In the larger sizes, so far as we have yet gone, we have invariably found increased economy, as in them the clearances are proportionately less, and it is easier to arrange the distribution of steam. Exceptionally low steam consumption is not the only essential attribute of an electric generator: there are other considerations, in most cases of more importance, these are steadiness of the current produced, freedom from accident, and simplicity, small first cost and cost of maintenance, little attention required, smallness of size and weight for a given output, and an almost insignificant consumption of oil.

To illustrate this, we will take the installation of the Phoenix Mills, Newcastle on Tyne, which has been running on the average of eleven hours daily for the last two years. Out of the original 159 Edison-Swan 16 c.p. lamps, 65 are still in good condition, having run 6,500 hours at about standard brightness. Now, if the lamps had only lasted 1,000 hours on the average, the cost of lamps renewed would have amounted to about double the year's cost of fuel as at present consumed.

At the Newcastle on Tyne Industrial Exhibition thirteen of these turbo-electric generators lighted the whole of the courts, giving a total of about 280 electrical h.p. During the whole run of the Exhibition the only noticeable accident which occurred to the installation was due to the blowing out of the packing in a branch steam pipe connecting another engine to the main steam pipe supplying the generators, but as there was no stop valve in this branch pipe the engineer in charge deemed it prudent to shut off steam at the boilers, thus stopping all the generators lighting the four courts for about three quarters of an hour. This, however, was an accident quite external to the generator, and, as it happened, external to the main steam pipe supplying them. We believe that it was only on three occasions during the run of the Exhibition that a small group of lamps were extinguished for the few seconds necessary to enable a spare generator to be started and switched on to them. The seventeen generators were in two groups, had they been placed in one group the results showed that on all occasions one spare generator would have been sufficient to keep every lamp alight.

In regard to simplicity and cost of maintenance, we may say that in a 30 h.p. generator there is no part that three men cannot lift, and that every part is immediately accessible. After two years' working, of ten hours daily, we have found the wear very small indeed, in some cases almost inappreciable, the blades or vanes show no signs whatever of any cutting action of the steam. The commutators in the larger generators have generally withstood this amount of wear, while in some cases where they have been carefully attended they have suffered very little wear indeed. We have at the present time some important experiments being carried out in regard to the generators. (For illustrations see next page.)

THE ELECTRICAL ENGINEER.

Published every Friday.

Price Threepence; Post Free, Threepence Halfpenny.

Editorial and Publishing Offices:
139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. Special Terms for a series can be arranged on application.

SITUATIONS VACANT and **"WANT PLACES"** Advertisements will be charged at **THREE WORDS for ONE PENNY**, with a **MINIMUM** charge of **SIXPENCE**.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months.	6 months.	12 months.
Great Kingdom	3s. 3d.	6s. 6d.	13s. 0d.
Within the Postal Union	4s. 4d.	8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 a fine steel engraved Portrait of E. GRAYES, Esq., President of the Society of Telegraph Engineers (Institution of Electrical Engineers), was issued. In future numbers we shall give a series of Portraits of other eminent Electricians of this century, including Portraits of Past Presidents of the Society of Telegraph Engineers. The next Portrait will be that of WOLLASTON, who flourished at the end of the last and the beginning of this century, and whose name has been immortalized by being applied to a particular form of battery designed by him. This will be followed by Portraits of PROF. D. E. HUGHES, F.R.S., and SIR H. DAVY.

PARIS, 1889.

It is a long time ahead that the Paris International Exhibition will be opened, but if the English electrical engineering industry is to be adequately represented, preparations must be commenced at an early period. We do not intend to weary our readers with the nonsense about exhibitions being necessary to the welfare of nations, of their having an educational value, and conducing to the peace of the universe. From our point of view all exhibitions must be considered from the stand-point—do they pay? will business be increased or decreased thereby? These questions appeal not only to individual exhibitors but to those engaged in the industry collectively.

At the Paris Exhibition in 1878 the great development of electricity—electric lighting—had hardly commenced. It was in fact the exhibits at that exhibition, and the stir made by the lighting of some of the streets around the Opera House by Paul Jablochhoff, that attention was directed to the possibilities of such lighting. A few years later, in 1881, showed the new departure in an exhibition solely devoted to its interests. Since then progress has been made by leaps and bounds, not only in the arc lighting but in the production of the incandescent light, a light far more suitable for interiors than the arc light.

A few facts connected with these early stages of the industry must never be forgotten. First, hardly any scientific or business man was prepared for the surprise of Jablochhoff in 1878; and secondly, those who should have known better were completely surprised in 1881 at the progress made in three short years. Between 1881 and 1889 is a space of eight years, and if Paris has already given us two surprises, will it not be best to prepare for a third? It is all very well to imagine that exhibitions are "played out," but we dare not act upon such vain imaginings. At this somewhat critical period of the industry, England must be well represented, unless indeed she is willing and eager to hand over to Continental rivals the position she has gained. It is well known that at present the Continental demand for our manufactures is good, and in order to retain this market it behoves us to show that we are well ahead of all competitors. Unfortunately, adequate representation means the outlay of large sums of money, and at this time profits are small, so that it is difficult for heads of firms or directors of companies to decide upon the outlay. Impenitency will not be paraded if there is a sufficient prospect of increased business as a return for the outlay. Other reasons are urged for not exhibiting. It shows competitors our designs, our work, our dodges. It allows them to copy, and so bring their wares up to a line with ours. The time has gone past for these arguments to have much weight. Exhibitions are a part and parcel of the world's commercial enterprise. Customers and probable customers are brought together from the ends of the earth. The warehouse is transformed from a back street, a three-

floor storey, or a country town, to—for the time being—the “hub of the universe.” Business men as a rule have to sell their productions now-a-days, not wait for customers to seek them out. Trade means going to the busy marts, to the highways and centres of industry, and by steady perseverance proving that the buyer must buy, and that he cannot buy better than of the seller.

Altogether, the consideration of the “pros” and “cons” must, we imagine, cause a decision in favour of the “pros.” Taking first the “cons.” The principal are “expense,” “making every competitor acquainted with our work,” “uncertainty of return,” “satisfaction with what we are now doing, and no desire to increase output,” “trouble and worry.” The “pros” may be given as “probable increase of business sufficient to cover all expenses and put something to the credit of profit,” “the showing of would be customers or old customers that the exhibitors’ productions are equal, if not superior to any other in the market,” “the making known the name and products of the firm, first from the number of visitors, secondly from the descriptions written for or by the press.” If figures could be obtained they would show that business done was strictly in proportion to the number of people making enquiries, or in proportion to the number of people knowing the firm’s productions. Once recognise that the outcome of exhibitions must be business, and that “gold medals” and other prizes are sought after as having a certain value to assist the sales, and all will be plain sailing. We deliberately, and after due consideration, have determined to treat these exhibitions from the purely business point of view. It is our duty and the duty of the technical press generally to do its utmost to describe and illustrate examples of industrial applications of the special branch it treats. The press is only a part of the business machine with certain and fairly well-defined duties to perform; one of these duties being an extremely sensitive regard in season and out of season to further the business interests of those engaged in the industry. The business house that attempts to ignore the value of technical journals as a means to promote greater activity in all branches of the industry, will in these times of fierce competition soon find itself relegated to the back-ground.

This brings us finally to the suggestion that the Institution of Electrical Engineers should take up the work of nominating a suitable committee, that this committee should be as representative as possible, and that from first to last the committee should consider the welfare of the industry. In France, in Germany, and in Austria it is customary to have representatives of the press upon committees, but hitherto in England these gentlemen have been thought better off than on committees. This example of other countries might with advantage be followed, as it would probably lead to greater interest being taken to completely represent the industry, and to describe the exhibits. The more

systematic and exhaustive such description the better for exhibitors and the public.

APPLIED SCIENCE IN THE DAILY PRESS.

Amongst the “infinite possibilities” of art, if not of nature, is the comic element in scientific journalism. Were we inclined to develop this, we might find ample opportunities in the utterances of the daily press whenever it takes up a question in relation to the application of scientific principles and discoveries. Amusement might be extracted from an enquiry into the perversion of the eternal fitness of things through which the writers have been called upon to treat such questions, or into the Rip Van Winkle condition of torpid non-observance in which they must have existed for years before they favour the public with their anachronous lucubrations.

The immediate occasion of our present observations is a recent article in the *Morning Post* in which, after a playful review of the negotiations between the City Streets Committee and “a Company engaged in spreading the new light,” and the ventilation of a fear, on the part of “many quiet and law-abiding folk, that there must be something uncanny in the prospect of a time when, so far as light is concerned, it will be always noon in the City,” the writer proceeds to enlighten the public with his own views anent the new light in question. He points out that “it”—the electric light—“is painfully intangible and mysterious; it cannot be seen or smelt like gas; though it is but fair to admit, on the other hand, that it does not testify its existence by violent explosion.” One might imagine that a light which, though “almost too brilliant while it lasts,” cannot nevertheless be either “seen or smelt,” would be sufficiently condemned: but, like the naval officer who was anxious to supplement the fact that he had no powder with forty-nine other reasons for not having fired a salute, the writer proceeds to point out other objections to the illuminant. It appears that “it”—the electric light—“cannot be measured out and distributed in convenient quantities for household consumption, as gas can.” The supply—whatever may be the views and conclusions of T. A. Edison and J. T. Sprague, *cum multis aliis*—must be in inconvenient quantities, presumably either too great or too small. Still there is hope; if not for the present at least for the future. “The system of accumulators opens out a wide prospect. It may be that, in years to come, the prudent householder will store up against the winter his stock of electric accumulators, just as the Irish peasant builds up his stack of turf.” Shades of Douglas Jerrold and Tom Hood! is there anything more funny, outside of the domain of scientific applications, than the picture of the prudent householder storing up his accumulators “just as the Irish peasant builds up his stack of turf”? Certainly there is something “uncanny” and “mysterious” about the accumulator referred to by the

Morning Post. "Stock of accumulators" is good, very good; but supposing that, as might happen with the turf, it became exhausted before the winter was out. The idea is a painful one; but fortunately we may find relief and consolation in the final conclusion of the *Morning Post* writer, viz.:—that, after all, the Electric Light "is so manifestly superior to gas as an illuminant that its ultimate success is assured."

The good things of the *Morning Post*, however, pale their ineffectual fires before a subsequent criticism of the *Daily News* upon Electrical Industry. It would occupy too much of our space to consider the *Daily News* article; but if readers conversant with the Electric Lighting industry are interested in exposing ignorance, they may well take in hand the article referred to which appeared on January 19th.

LITERATURE.

A course of Lectures on Electricity, delivered before the Society of Arts by GEORGE FORBES, M.A., F.R.S., LL.D., &c. [London: Longmans, Green and Co.]

It is generally understood that a little heaven lighteneth the whole lamp, and the same may apply to scientific books, a few good ones will perhaps pave the way for the whole to be good ones, though the time occupied in educating purchasers will cause the grist in the authors' mill to be very meagre. Prof. Forbes has in this book given information relating to electrical matters which the student will not have to unlearn when he leaves the student for practical life. The reader has here a good solid foundation, upon which he may build without danger to the superstructure. It is only during the last few years that books of this kind have been issued. Most of these, however, which we could recommend have been written more for use in schools than for the general reader. Prof. Forbes' book has been written from quite a different point of view. The basis of the work was the shorthand notes taken during a course of Cantor lectures before the Society of Arts. These notes have been elaborated and altered to their present form. The scope of the work will be gleaned from the following sentence:—"The lectures were primarily intended for an intelligent audience, ignorant of electrical science, but anxious to obtain sufficient knowledge of the subject to be able to follow the progress now made in the science" *vide* Preface. The number of people who could listen to the lectures was limited, the number they appealed to is very large, and we must acknowledge that the design of the author has been well carried out. The information given is just that required by an intelligent reader—not descending to the frivolous, nor soaring into the transcendental, but clearly placing the broad, fundamental facts of the science within the grasp of the reader.

The first lecture treats of potential and electromotive force, the illustrations and experiments being mostly taken from the domain of static electricity. It may perhaps be well here for us to illustrate the author's method and style by the following extract (p. 13):—"When those powerful generators of electricity called dynamo machines are at work we often speak of the difference of potential at the terminals or at the brushes. The expression will be so often used in describing electrical phenomena that I will now say a few words about it. It is a comparatively new expression in scientific language, but one of great importance. We know that the force of gravity gives velocity to a falling body, and the body acquires energy of motion—*kinetic energy* it has been called. But when a body is raised from the floor to the table it acquires energy of position, not of motion, because it has the power of falling to the floor, and so doing a certain amount of mechanical work. How are we to define the energy which exists in a ball when placed on a table? It has a potency of doing work. It has what Rankine called potential energy, and

the word expresses very well what we mean. Suppose a ball be thrown up in the air. At starting it has kinetic energy, energy of motion, which gradually diminishes and disappears, giving place to energy of position at the top of the ball's flight when the ball has no motion. The great principle of the conservation of energy tells us that at each part of the ball's flight the sum of these two energies remains the same (neglecting the slight dissipation of energy by friction with the air). You understand then what we mean by potential energy. The difference of gravity potential between the floor and the table is measured by the energy given off by a unit mass falling from the table to the floor, or by the work that is done in raising a unit mass from the floor to the table.

"If now I have a piece of glass positively, and a piece of silk negatively, electrified, some work must be done in moving a body with a unit charge of positive electrification from the silk to the glass. This measures the difference of electric potential between the glass and silk.

It will be sufficient if we now indicate the contents of the succeeding chapters. The second lecture deals with electric current and resistance, the next with magnetism, the next with electromagnetism, the fifth being on electro-magnetic induction, and the work concluding with a lecture delivered at Philadelphia on dynamo-electric machinery.

It will be seen that the ground traversed is such as to prepare the reader for the practical work of electric engineering, and especially in those branches which have been so rapidly developed during the past three years. It is hardly necessary to say that the work is well illustrated and printed.

EDISON AND SWAN COMPANY'S MINER'S LAMP.

The lamp (Fig. 1), which was referred to in the article by Mr. Swan in a previous issue, consists of a storage battery

FIG. 1.

FIG. 2.

of four cells (Fig. 2), enclosed in a strong teak box turned out of the solid and strengthened with metal bands (B), and a small incandescent lamp mounted on the side of the

FIG. 3.

case, protected by a strong glass cover (C). The case is fitted with a hinged lid secured by a cross bar fastened with a safety nut (F), and having a swivel handle (D). The

full size of the lamp is 7in. by 4½in., and the weight of the whole ready for use is about 6lbs. 13oz. The lamp is opened by unscrewing the safety nut (F) by means of the key (Fig. 5), and lifting the lid which turns on the hinge (G). Then by means of the small key (Fig. 4) the battery can be withdrawn. The battery of four cells or accumulators, joined in series, has the terminals brought down the sides

FIG. 4.

FIG. 5.

of the battery (as shown at H) in the form of two contact plates, which, when the battery is put into the case, come in contact with two corresponding plates in the case, and so convey the current from the battery to the small incandescent lamp. Fig. 3 shows the frame in which the battery stands while being charged with current from the dynamo. The lamp may also be had with fire damp indicator attached. This indicator is a modification of Mr. Lievings.

KENNEDY'S DYNAMOS.

Another type of dynamo designed and introduced by Mr. Kennedy not referred to in our article last week is what he terms his C type, and is more especially designed for ship lighting. As will be seen from the illustration, this

Rankin Kennedy's New C-Type Dynamo.

design is really a double dynamo, two complete dynamos in one machine, the space occupied by the double machines not being much more than that taken up by the ordinary types. This machine has been introduced where a saving of space is a great object, such as in ship-lighting. Again, the armature of a single machine has often been rendered useless during a voyage, and in order to obviate a difficulty of this kind, duplicate machines have been installed in a ship. By the arrangement of Mr. Kennedy one half of the machine would be able to do the work while the other half was being repaired, so that in fact the whole consists of what may be termed a modified set of duplicate machinery. It is unnecessary to enter into detail as to the construction of this machine, as except in its mechanical modification it is similar to the single armature machine.

NOTE ON WATTS AND HORSE-POWER ELECTRICAL.

BY DESMOND G. FITZ-GERALD.

Misapprehensions as to the value in watts of the horse power electrical have occasionally arisen in consequence of the following relations, viz. :—

1. The horse power electrical, taken as 746 B.A. watts, is equivalent to only 736 true watts.

2. The horse-power electrical is equal to 756 B.A. watts.

3. The horse-power electrical is equal to 746 true watts.

In absolute C. G. S. e.m. units, taking the force of gravity as $g = 981$ dynes, Watt's horse-power of 550 foot-lbs. per second is 7.46×10^9 ergs per second.

The watt (ampere \times volt) = $10^{-1} \times 10^8 = 10^7$ ergs per second.

Thus we have, as the value in true watts of the horse-power electrical

$$\frac{7.46 \times 10^9}{10^7} = 746.$$

If our standard expressing the volt be too small, and that expressing the ohm also too small proportionately, current, in the expression (ampere \times volt), will not be affected, but our watt will be affected by our standard of e.m.f., and will consequently be too small. Since the standard of e.m.f. corresponding to the B.A. standard of resistance is .98677 true volt, 746 B.A. watts will be $746 \times .98677 = 736$ true watts; and $\frac{746}{.98677} = 756$ will be the value in B.A. watts (or

in watts as measured by the B.A. standard of resistance) of the electrical horse power.

The "force de cheval," which is adopted by some electricians in this country, as well as abroad generally, is defined as 75 kilogrammetres = 7.36×10^9 ergs per second. It is therefore 736 watts, and thus happens to be the same

as what may be called the B.A. horse-power—i.e., that of 746 B.A. watts.

Judging Colours. The *Chemical Trade Journal*, in ostensibly discussing the question of dynamos and electro-motors while in reality describing Cuttriss's dynamo and motor, says: The dyer, the calico-printer, and paper-maker has often before him the task of judging minute differences in colour shades, and if the day is at all dull it is next to impossible to do so accurately, and to attempt to judge by the light afforded by ordinary coal gas is out of the question altogether. Having power at hand, the possession of a small arc light is a problem of the simplest character, and satisfactory results may be obtained with the minimum expense. Incandescent lamps will not answer satisfactorily for colour judging, and though it has been stated that glow lamps may be used, yet those who have employed them for this purpose give anything but a good account of them. Several calico-printers in the neighbourhood of Manchester have already adopted arc lights in some portions of their establishments, and we have seen the same working in a most satisfactory manner in more than one works; still, most mills are fitted throughout with gas, and it requires very strong pressure to induce a manufacturer to change from a system he has had in operation so long.

ELECTRICITY IN ITS RELATION TO THE MECHANICAL ENGINEER.*

BY FRANK G. H. BABCOCK.

Yet another great force, or manifestation of force, in nature is already yielding its neck to the yoke prepared for it by the mechanical engineer. Electricity had long been known as a terror, and had been played with as a toy, but our own Franklin, in this very city where we are now assembled, was the first to show that the terror and the toy were one. Other ready hands took up the work of subduing it, and now it rings our call bells, lights our gas, watches sleeplessly in our dwellings for burglars, regulates the heat in our rooms to a fraction of a degree, makes our plated ware and electrotypes, duplicates our medals, and starts our exhibitions at the nod of a president or a king a thousand miles away. It floods our streets and public halls with light, and furnishes a tiny fire-fly lamp to explore the inner recesses of our bodies. It drives our sewing machines and our street cars, and is even trying its hand at boats and railways. It concentrates into a point the heat equivalent to 500 horse power of work, and vaporises metals we have scarcely been able otherwise to melt. It welds together rods and shafts, as it were, with a touch, and smelts the most refractory ores.

But I need not enumerate the wonders which mechanical genius and skill have wrought in this our day, in the line of the first grand commission to "subdue the earth." You see them all about you.

The question only remains. What will be the outcome? To what shall we look forward as the field for future achievement? Can we go on at the same rate of advancement, or must we stop for want of other worlds to conquer? Towards the end of the last century—after Priestly had discovered oxygen—Galvani had found the supposed secret of life, the Leyden jar had shocked crowned heads as well as philosophers, Watts had brought steam into practical use, Arkwright had invented the spinning frame and Cartwright the power loom, Murdoch had begun lighting buildings by gas, Cort had invented the puddling furnace and the rolling mill, and Tennant had produced chloride of lime and applied it to bleaching purposes—a prominent scientist said that there could be no probability that the next age would advance as rapidly as that had done. But discovery has followed discovery in a geometrically progressing ratio, until, at the present time, we stand aghast, and say, "What can come next?" It is, however, probable that the future will bring many a discovery and application of knowledge, as far beyond anything we can now imagine, as sewing machines and mowing machines, railroad and steamships, celluloid and dynamite, rock drills and rotary printing presses, vulcanised india-rubber and Bessemer steel, boring for oil and burning water-gas, photography and the phonograph, electric light and electric smelting, the telegraph and the telephone, the spectroscope, and hundreds of other discoveries and inventions of the nineteenth century were beyond the thoughts of our grandfathers one hundred years ago.

But though we cannot foretell what wonderful things may be in store for us in the future, we may at least speculate a little, based upon the knowledge we now have. I have spoken of the probable exhaustion of our coal fields and the necessity of finding some substitute. There is a source of heat fully capable of supplying all we need, if it can be utilised; that is the sun. It has come to be generally admitted that coal is in a sense nothing but condensed sunlight stored up in ages past for our present use. Now, if we can only devise means for imprisoning the heat of the sun, so as to use it as we may need it, then we can abandon our coal mines and forget that they ever existed. The amount of this heat in one minute, as determined by the United States expedition to Mount Whitney, is sufficient to heat one gram of water three degrees centigrade for each square centimetre of the exposed surface of the earth. But this conveys little idea to the mind not educated to think in such measures. It may be better understood if we say that it is equivalent to the heat generated by the combustion

tion of, in round numbers, one thousand millions of tons of coal for every minute in the year; or one million three hundred thousand times as much as is now mined.

Already an honoured member of our Society, Captain Ericsson, has shown us how a portion of it can be conserved. But the question may be asked, What would be the result upon the condition should this heat, which now goes to warm the earth and promote vegetation, be used for other purposes? To this it may be answered, that, as the earth does not grow warmer year by year, all the heat it receives must either be changed to other forms of energy or be radiated into space. It is likely, therefore, that the heat radiated from the earth is nearly as great as that received, and possibly some way may be discovered to catch it on its outward journey, if it be found that the amount necessary for the purpose would rob nature of her share. But, as the burning of 400,000,000 tons of coal, and probably as much more wood, upon the earth, per annum, does not seem to perceptibly alter the character of our seasons, it is probable that a similar amount taken from the heat received from the sun would not produce a noticeable effect upon the processes of nature.

But we must learn to conserve our heat better, and instead of the present wasteful mode of making power by means of steam, by which only one-tenth of the heat generated is utilised, some better means must be discovered of turning heat into work. The generation of electricity directly by the combustion of coal has often been suggested as a possible thing, and one of our members, Mr. Edison, is even now working with some success upon the problem. Should future genius succeed in utilising the heat as fully in a thermo-electric generator as is now done in our steam boilers, the coming age will get its power at one-fifth the cost of the most economical engines of this day, and then, if the radiant heat of the sun can be caused to take the form of electrical force, factories, railroads and steamships will be driven and lighted with no expense beyond the interest and wear and tear of the machinery.

It is not, however, necessary for us to wait for the discovery of this efficient thermo-electric generator before we can conserve our fuel. We now have means by which the water power, which is going to waste, can be transmitted to localities where more power is demanded. Electric dynamos have attained to as high as 90 per cent. efficiency, and if they can be made perfectly reversible, which, at least, seems probable, we should be able to transmit power with comparatively small loss. The water power of the world is estimated at 200,000,000 horse-power, and when we shall have conserved this we shall have enough to supply the world's work for years to come, then there is the enormous energy of the tides and of the winds, which might be added thereto, when we have perfected storage batteries, so that the extremes of effort of such forces may be graded down into a constant mean.

In looking about for fields to conquer, the question springs to the mind, Shall we ever fly? That has been one of the dreams of mankind from the earliest ages. He has looked upon birds as they have sailed through the air, apparently without effort, and has wondered why he could not attain the same mode of motion. Why not? It is simply the question of sufficient power within a given weight. The weight of our steam engines per horse-power has been decreased 37 per cent. in the last five years, and we are not at the end. We are also reducing very rapidly the weight of our dynamos and electric engines in proportion to their power, so that it is now but one quarter of what it was five years ago. When man has learned to generate power with, say, one-tenth the weight of apparatus that is now required, then, by making the framework of his flying machine of aluminum tubes, there is no good reason to doubt that he will become master of the air, as he is now master of the water, and will be able to fly from place to place with all the certainty and safety of a bird.

But I will not detain you by any further speculations as to the future triumphs of our profession. That they will be great does not admit of a doubt in view of the past. That they will be more wonderful and important than we can now comprehend is probable from the analogy of history. That they will elevate and ennoble man, lift him

* Portion of opening address at the meeting of the American Institute of Mechanical Engineers, Philadelphia, Nov. 23, 1887.

out of many of his present limitations, and make him the master where he now is the victim is certain, because that has always been the effect heretofore, and because it is the end for which the engineer is commissioned. This society is to be a factor in such result. Its every meeting to mingle experiences, to discuss causes, to compare attainments, and to encourage research is a step toward the final achievement, when every force of nature and every created thing shall be subject to the control of man. *Electrical World.*

THE ELECTRIC LIGHTING OF THEATRES.

BY DR. G. SOUS.

(Continued from page 51.)

Spasm of the ciliary muscle, producing temporary myopia, can only be the consequence of the intensity of the light. The pupil contracts in order to diminish the quantity of light reaching the eye, and the connection between the iris and the ciliary muscle is so close, although not identical in different individuals, that we may say that the contraction of the iris has brought about the contraction of the ciliary muscle.

The cases of temporary *convergence*, which have been indicated by M. Javal in professional electricians, may, perhaps, be occasioned by the production of the gases referred to by M. Frenzel. I advance this as a question without having the pretension to offer a solution, as I have before me no case in my private experience.

The cases indicated by Nachter, Rockcliffe, &c., are of greater importance. It is here a question of lesions affecting the sight, and *provisi facit* one is inclined to consider these lesions as being analogous to those observed after direct insolation of the eyes.

After observing eclipses of the sun, after astronomical inspection of this body, and after nautical observations with a sextant, many persons have experienced unpleasant symptoms produced by the intensity of the solar light. Many cases have been published, and I have myself investigated several more, especially at the period of the eclipse in 1882, or in the case of medical captains who had passed a lengthened period in the equatorial regions when becalmed. When these cases, evidently due to the intensity of the light, are studied, it is observed that the disease is not attended with any intense pain in the eyes, and that central *scotomata* of greater or less extent are present, and may persist in darkness. Persons who have occasion to examine the carbons in arc lights experience other symptoms, namely, violent pains in the eyes and photophobia. Thus in 1880 I noted the following fact: On the 14th July M. D. had installed at the Nantes Hotel a system of lighting which he had patented under the name of the inextinguishable electric candle. In order to observe the separation of the carbons and the action of the apparatus, M. D., whose eyes were provided with dark blue glasses, frequently looked closely into the electric light. During the night he was seized with violent pains in the eyes. He seemed to perceive the burning carbons, and not only with his eyes but within their orbit. The weakest light had become intolerable, owing to its increasing the pain. It was in a completely darkened room, and without being able to make any examination, or even to perceive anything whatever, that I was called upon to meet the patient, and to hear the account of his sufferings and his experiences. I prescribed compresses saturated with water of the cherry laurel, permanently applied, and after two days all the symptoms had disappeared, the cure being complete. In the employment of blue glasses M. D. made a complete mistake. Blue glasses diminish the intensity of light, but allow of the passage of the blue and violet rays. The progress of the lesions produced by the direct rays of the sun are altogether different. In such cases, as is shown by the experiments of Czermak, the layers of the retina may be destroyed and be replaced by pigmented connective tissue, hence the persistent and sometimes obstinate *scotomata* which are observed.

If the electric rays give rise to phenomena differing from those produced by solar light, the cause is to be attributed not to their luminous intensity, but to the chemical rays and the fluorescence resulting from their action. "The artificial lights at our disposal, which are much weaker than the light of the sun, say Alglave and Baudard, are not injurious by reason of their intensity, but owing to their particular character." ("The Electric Light" page 160).

Regault and Foucault have indicated fluorescence of the cornea produced by chemical rays. Dr. Chardac has assumed that the physiological function of the crystalline lens is to intercept all ultra-violet radiation. This conclusion is too general, for Donders, Rees, Brücke, and Helmholtz have made known experiments which establish the fact that the violet and ultra-violet rays may reach the retina, and that this organ does not escape fluorescence.

Fluorescence of the retina, of the cornea, such is the cause of the symptoms observed after the direct action of the (arc) elec-

tric light. It is impossible to take too great precautions against this injurious effect.

The cause being known, we have the remedy to hand. It is by surrounding the eye with protective substances, by preventing their effects by means of screens, that we shall obtain the desired end. The light must be modified by means of glasses, or else the apparatus must be so arranged as to give only reflected light.

"Lighting," says M. Trélat, "is properly carried out only when the eye is shielded from the immediate effect of the luminous source. The eye when exploring the illuminated space should never be directly exposed to the luminous focus. When small sources of light only are at our disposal we are obliged to bring them into close proximity to the space to be illuminated. In this case it is difficult to prevent the direct rays from reaching the eye, but with electric lighting, properly understood, it is easy to do so. It suffices to have the luminous foci sufficiently intense, and to place them at a sufficient height."—"Medical Progress," 1881.

In order to shield their eyes from the luminous focus, the readers at the British Museum library adopted a means which would scarcely be practised in a theatre. We read the following in the *Journal Universel de l'Electricité* for the year 1886, in relation to the above library: "Several of the readers protect themselves against the rays from the lamps by means of sunshades."

At the theatre suitable glass globes would be more convenient than sunshades.

All these globes made of more or less opaque glass, enamelled or ground glass, &c., augment the surface of the luminous source, render the shades less hard by the extension they give to the penumbra; but they absorb more or less light according to their arrangement and their thickness. When any substance is rendered translucent instead of transparent, light is always screened. The use of these globes may be continued, but in the illumination of theatres the lower portion only should be rendered partly opaque, leaving the whole intensity of the light to be radiated upwards to the ceiling. In this manner the foci would be subtracted from direct vision, and the spectators would receive only the light reflected from the upper portion of the enclosed space.

As the ceilings of theatres are not plane surfaces it may be well to examine what should be the position of the electrodes constituting the main source of illumination. The ceiling may be related to the circle or to the ellipse. I speak here of the generatrix of its surface, and not of the form of its limiting curve.

If the generatrix be a circumference, the ceiling becomes a concave mirror, and by placing the electrodes midway on the radius of curvature all the luminous rays will be reflected perpetually into the enclosure, and will not directly reach the eyes. If the generatrix be an ellipse, the foci of the ellipse must be located where there are no spectators—in front of the upper seats, for instance. If, from each focus of the ellipse a line be drawn to the limit of the ceiling, we shall have a surface limited above by the ceiling, and below by the intersection of the lines drawn from the foci. It is in this surface that the electrodes should be placed. In this case the maximum of the rays reflected by the ceiling will be at the foci of the ellipse—that is, at a place where they will not meet the eyes of any spectator.

In lieu of opaque globes coloured glasses might be employed. The utility of these glasses is in modifying the spectral composition of the electric light. Yellow glasses might here be useful, not with a view of producing a yellow light such as would occur in the case of a source of white light, such as the sun or magnesium.

Yellow glasses may be obtained in different ways. Chromium, carbon, antimony, uranium, and various salts of silver are substances, which, when added to ordinary glasses, produce a yellow coloration. They are not all of the same value in relation to the chemical rays. Those manufactured with uranium obviate fluorescence, but they are dichroic, and would thus have a bad effect in theatres. Chromium glass is to be preferred, for it removes the most refrangible portions of the spectrum, in other words it destroys the blue and violet rays of the spectrum, and consequently the chemical rays.

According to Dr. Stone, *Journal Universel de l'Electricité*, July, 1884, the electric light is detrimental to the eyes, that which is produced by the voltaic arc is in consequence of the excess of chemical rays, and that from incandescence lamps by reason of a preponderance of carbonic rays. In order to neutralize these effects, an oculist has had manufactured spectacles framed of blue and red glasses. The blue glasses are placed in front and the red glasses at the sides. The blue glass is used when the light is produced by incandescence, and when this is due to the voltaic arc the red glass is folded over the blue glass. These spectacles are but little known in France.

THE LIGHT BY INCANDESCENCE.

It has been said that the voltaic arc gives *wholeness*, and the incandescence lamps *total illumination*. In point of fact the former is adapted for large spaces, and the latter for spaces of

restricted dimensions. There are, however, other differences. The incandescence light is more steady, more continuous, and less flickering. It is less intense, and moreover, from its spectral composition, it approximates closely to the illumination our eyes are accustomed to. Thus, a 10-candle incandescent lamp surpasses a Carcel lamp only by two candles at the most. Thus we see these lamps in use without opaque glasses in dwelling houses and at theatres. It is, in fact, in this direction that their useful application lies, and they advantageously replace less effective methods of illumination without having any detrimental effect so far as has been observed.

In most theatres 10 candle incandescence lamps have most generally been employed. At the opera there are 165 Edison 10 candle lamps equivalent to 200 Candles. Under these conditions the precautions to be taken are merely those which would be advisable in any general case of lighting.

To sum up, the light from the voltaic arc, containing a large proportion of chemical rays, is detrimental to the eye. It supplies a powerful and energetic method of illumination. It is adapted for public spaces, for enclosures of vast extent, and necessitates that precautions should be taken to obviate its detrimental action. The light obtained by incandescence is more steady and less intense, it resembles in its spectral composition the ordinary artificial lights, and its possible drawbacks are merely such as would be due to an excess of any artificial illumination. It is the light best adapted by its nature and degree of intensity for the illumination of apartments and meeting places, and it is with good reason that it has been preferred generally for the illumination of theatres.

PORTABLE VOLTMETERS FOR MEASURING ALTERNATING PORTABLE DIFFERENCES.

BY PROFESSORS W. E. Ayrton and JOHN FERRY.

(Continued from page 34.)

E.—UNIFORMITY OF THE SCALE DIVISIONS.

It is rather important to notice that from (9) it follows that the smaller is γ , the more uniform become the divisions of the scale.

Now from (15), $\gamma = \frac{1}{4} \frac{l}{L} \frac{p_0}{q} \phi_1$; so that γ being small means, since $\phi = \frac{b}{a}$, that $\frac{1}{4} \frac{l}{L} \frac{p_0}{q} \phi_1$ is small, or that $\frac{1}{4} \frac{l}{L} \frac{p_0}{q}$ is small. But as a large maximum value of the deflection is very important, and as this, as we have seen, requires that l and r should be small, and that l and q should be large, the only way in which we can simultaneously satisfy both sets of conditions is to make a large—that is, by using thick wires, many wires (as many wires as possible), and very thin strips for our magnifying spring. Using thick wires, however, diminishes the range of volts that can be measured.

Finally, it is to be observed that the condition of most importance in obtaining

- (1) A large maximum deflection,
- (2) Uniformity of the divisions of the scale,
- (3) A large range of volts that can be measured,

is to make the strip of which the magnifying spring is made as thick as possible.

F. CORRECTION FOR TEMPERATURE.

In what proceeds we have disregarded the effect produced by variation of the temperature of the instrument as a whole, caused partly by variations of atmospheric temperature, and partly by the warming up of the whole instrument by a prolonged maintenance of the potential difference at its terminals. We will now investigate the magnitude of the error so caused.

Let α be the coefficient of expansion of the stretched wire.

Let β be the coefficient of expansion of the framework supporting the ends of the wire.

Let θ be the dip θ (Fig. 10) at the temperature of graduation.

Let θ' be the dip at the temperature t above θ .

Let θ'' be the dip at the temperature t' above θ .

Let θ''' be the dip at the temperature t'' above θ .

Let θ'''' be the dip at the temperature t''' above θ .

Let θ''''' be the dip at the temperature t'''' above θ .

Let θ'''''' be the dip at the temperature t''''' above θ .

Let θ''''''' be the dip at the temperature t'''''' above θ .

Let θ'''''''' be the dip at the temperature t''''''' above θ .

Let θ''''''''' be the dip at the temperature t'''''''' above θ .

Let θ'''''''''' be the dip at the temperature t''''''''' above θ .

Let θ''''''''''' be the dip at the temperature t'''''''''' above θ .

Let θ'''''''''''' be the dip at the temperature t''''''''''' above θ .

sation of the framework of the instrument for changes of temperature. Hence

$$\gamma = \gamma_0 \left(1 + \frac{1}{2} \alpha \theta + \gamma t \right) \quad (17)$$

Also, if ρ_0 be the specific resistance of the material of which the wire is made at the temperature of the framework of the instrument during graduation, and if ρ be the specific resistance when the framework of the instrument is at a temperature t C. above that of the temperature of graduation, and when the wire has a temperature θ C. above that of the framework,

$$\rho = \rho_0 \{ 1 + \lambda (\theta + t) \}.$$

Consequently, following the reasoning previously given, connecting the rate of loss of heat by radiation and convection, and the rate of production of heat by the passage of the current, we have

$$\theta = \frac{I^2 d}{4 l \rho \{ 1 + \lambda (\theta + t) \}} \quad \text{approximately.}$$

Substituting in (17) the value for γ given in (b), and for θ the value just obtained, we have

$$\begin{aligned} \phi^2 + 2 \gamma_0 \phi &= \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}} \left(1 + \frac{1}{2} \alpha \theta + \gamma t \right) \\ &= \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}} \left(1 + \frac{1}{2} \alpha \theta + \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}} t \right) \\ &= \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}} \left(1 + \frac{1}{2} \alpha \theta + \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}} t \right) \end{aligned}$$

$$\phi^2 + 2 \gamma_0 \phi = \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}} \left(1 + \frac{1}{2} \alpha \theta + \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}} t \right) \quad (18)$$

approximately. Now formula (8), obtained on the assumption that the framework of the voltmeter always remained at the temperature it was at during the graduation of the instrument, may be written

$$\phi^2 + 2 \gamma_0 \phi = \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda \theta \}}.$$

hence the effect of the whole instrument being heated up to t C. is to diminish the right hand side of the equation by the fraction $\frac{\lambda t}{1 + \lambda \theta}$ of itself, in consequence of the increase of the resistance of the stretched wire; and to increase the right-hand side of the equation by the fraction $\frac{\gamma t}{1 + \lambda \theta}$ of itself, in consequence

of the difference of the coefficients of expansion of the stretched wire and the framework. If γ , the difference between the coefficients of expansion of the stretched wire and of the framework be selected so that

$$\gamma = \frac{\alpha \lambda \theta}{1 + \lambda \theta}$$

then for that particular value of θ there will be no temperature error of the instrument. Now the effect of γ not being sought will be to cause a slight motion of the pointer when the whole instrument is warmed up as a whole without any potential difference being maintained at its terminals, or, in other words, γ produces what may be called a zero error. Hence the zero error can be made such that there is no temperature error when the instrument is required to measure a certain definite potential difference or a potential difference of about that value. If, on the other hand, the framework of the instrument be so constructed that γ is sought—that is, so that there is no zero error—then the deflection corresponding with any given number of volts maintained at its terminals will be somewhat diminished as the instrument warms up as a whole. In order that accurate readings may be able to be made of small potential differences giving deflections near the zero, it will be desirable to make γ small, but whether it ought to be made absolutely sought or not can only be determined by practical experience of this new form of voltmeter extending over some time.

Solving (18), we have

$$\phi = -\gamma_0 + \sqrt{\gamma_0^2 + \frac{I^2 d}{4 l \rho_0 \{ 1 + \lambda (\theta + t) \}}} \quad (19)$$

and in order to estimate the magnitude of the error arising from the terms involving t let us consider the values of the constants in the previous expression. In some of our instruments we find that the initial sag d is about 0.5 centimetre, and that α is about 0.22 centimetre when ϕ is about 280—that is, when the needle is deflected to the limit of the scale. Therefore, since

$$\phi = \frac{V}{r},$$

$$\text{and } \phi = \frac{V}{r} \left(\frac{1}{1 + \lambda \theta} \right),$$

it follows that $\phi = \frac{\phi_0}{2}$, approximately,

when the deflection has about its maximum value. Hence, if we write X for $\frac{1}{1+k\theta}$ X' for $\frac{1}{1+k\theta} \left(1 - \frac{k\theta}{1+k\theta} + \frac{\gamma\theta}{\alpha\theta}\right)$ and ϕ' for the value of ϕ when X becomes X' , we have

$$\phi = 2\phi' + \sqrt{4\phi'^2 + X}, \text{ approximately,}$$

$$\text{and } \phi' = -2\phi' + \sqrt{4\phi'^2 + X},$$

therefore the proportional error when the deflection is a maximum

$$\frac{\phi - \phi'}{\phi} = \frac{\sqrt{\frac{X}{5}} - \sqrt{\frac{X'}{5}}}{\sqrt{\frac{X}{5}}}, \text{ approximately,}$$

$$= 1 - \sqrt{1 - \frac{k\theta}{1+k\theta} + \frac{\gamma\theta}{\alpha\theta}},$$

Now k equals 0.00031 and α about 0.000145 for platinum-silver; also θ is about 250° C. when the deflection ϕ is about 280°. Let t , the temperature through which the case of the instrument is raised above the temperature of graduation, be 50° C.; then, if γ be sought,

$$\phi - \phi' = 0.007, \text{ approximately;}$$

that is, ϕ is diminished by about 0.7 per cent, in consequence of the increase of resistance of the stretched wire. And this temperature error can be made still less by giving γ a negative value—that is, by making the framework of the instrument have a larger coefficient of expansion than the stretched wire. For instance, if the framework which carries the stretched wire have a coefficient of expansion rather less than that of copper, the temperature error of the voltmeter in the higher parts of the scale will be practically nought.

The accuracy of the instrument depends, among other things, on the constancy of the elasticity of our magnifying springs. To test this we have had tests conducted regularly during the last two years on one of our magnifying spring ammeters. The current was measured absolutely on each occasion by the silver-deposit method, and, as this can be done more easily and accurately if the current be rather small, the ammeter selected for this series of tests was one that gave the maximum deflection (of about 270°) for 1½ amperes. Of course the only difference between this ammeter and a magnifying spring ammeter measuring a much larger current is in the gauge of wire used in the winding, and not at all in the spring; therefore any conclusions as to constancy that may be drawn from the results of the tests are equally applicable to any other magnifying spring ammeter. Sixty-four distinct tests have been made by different groups of students in the two years; and to impress on the students the importance of making such time tests of an ammeter, as well as to prevent their imagining that the silver-deposit test ought to give the same values for the currents as are indicated by the graduations of the scale of the ammeter, the students were warned that the ammeter had been intentionally graduated with an error—the error, in fact, being that the ammeter reads from 1½ to 2 per cent, too low.

Instead of giving the tests in the exact order in which they were taken, each group of tests is, for convenience of comparison, arranged in chronological order. (Table A.)

As the tests were made by a large number of different students, having very different aptitudes for such work, some of the results arrived at were obviously wrong, and have been rejected, but, excluding these few exceptional ones, the preceding are a fair sample of the results obtained, and we see that it is impossible to conclude from them whether the ammeter has become more or less sensitive during the two years. In other words, its sensibility for practical purposes has remained quite constant. The temperature was carefully recorded after the early part of 1886, since it was thought that perhaps some temperature error might become visible, but this has not turned out to be the case, so that the temperature may be apparently neglected in using a magnifying spring ammeter. With a magnifying spring voltmeter wound with copper wire there will, of course, still remain the error due to a variation of the resistance of the coil with temperature, but the important result that has been arrived at is that the *advantages of a magnifying spring ammeter or voltmeter, when a given current is passing through it, is not altered by age or by the ordinary changes of temperature of a room.*

To further test this latter point a magnifying spring ammeter, adjusted so that the needle stood exactly at zero when the temperature was about 15° C., was placed in a bath and heated up to 40° C. for five hours, but no change in the zero could be observed, which would have been the case if the elasticity of the spring had sensibly varied, seeing that the weight of the soft iron cylinder was hanging at the end of the spring all the time.

We feel, therefore, quite safe in using the magnifying springs for our new type of voltmeter.

TABLE A.—Tests made with a Magnifying Spring Ammeter initially graduated from 1½ to 2 per cent, too low.

We are now engaged in devising various means for compensating this new form of voltmeter for temperature errors; but before actually introducing these compensations into the instruments one of our students, Mr. Kilmour, has been carefully measuring the exact coefficient of expansion with temperature of fine platinum silver wire under a tension which is comparable with its breaking tension. The compensation for the short tube form shown in Figs. 3 and 4 will probably in part consist in the device adopted by Captain Cardew of making the support to which the wires are attached of a compound metal, while in the case of our bicycle-wheel form the rim to which the wires are attached will probably be made like the balance-wheel of a chronometer, but, of course, the same accuracy of adjustment for temperature that is necessary in a chronometer will be quite unnecessary in the voltmeter, as the error is not a cumulative one as it is in a chronometer.

The following, we venture to think, are the improvements that we have been led to introduce into the Cardew voltmeter by employing the devices that we have described.—

1. A small alternating potential difference can be accurately measured, as the wire in our instrument may be short, and as the readings can be taken down to the zero with certainty.
2. With the same instrument a wide range of volts can be measured, since with many short wires combined with a commutator any number of them can be put in series; that is, any length of wire can be electrically used.
3. Whatever number of volts is being measured, all the wire is directly active in deflecting the pointer, which is not the case with an instrument provided with an external resistance for increasing the range.

4. The instrument is compact and portable.
5. Great dead beatness of action is secured by the employment of much finer wire than has hitherto been commercially used, and by the magnifying gearing being frictionless and comparatively massless.
6. Non liability of even such fine wire to break from a blow, in consequence of the frictionless and comparatively massless character of the magnifying gearing to which the wire is attached.
7. Diminution in the power wasted in the instrument by the employment of a short instead of a long wire.

INSTITUTION OF ELECTRICAL ENGINEERS.

PRESIDENTIAL ADDRESS.

(Continued from page 57.)

The operations of the telephone as yet are of a more limited character, but even as at present developed are of little less interest. The telegraph may be regarded, in the main, as the rapid public transmission of private or public correspondence; the telephone as the instrument of personal, and therefore necessarily private, communications between man and man. If the communication is perfect, and so arranged as to be free from interference, not only can the varying sounds of voices be recognised through the connecting wire, but the tones may be distinguished in many cases, and the speakers known. One individual can speak freely to another, obtain his answer, and make any response he thinks fit. An entire business transaction can be completed without any rearrangement, and confidential questions can be equally confidentially replied to. It is advanced the discovery of the means of transmitting the effects of speech to the verge of success, but did not pass the verge. Bell completed what Reis had begun, and placed a workable instrument at the disposition of the world. Edison and Hughes strengthened the forces employed for the transmission of sound waves, and the telephone (as we know it) was completed. Founded upon the laws that guided the production of the telegraph, the generation of the telephone was especially rapid; but a brief space has elapsed between its inception and its realisation. The marvel it has wrought is less striking than those of the telegraph, but the processes by which they are produced appear more marvellous still. At present the operation of wire-stretching patents perhaps excepted, to some extent, the improvement of the mechanical apparatus needed for telephonic expression, and time has not sufficed to admit of difficulties in the way of its extended use being overcome; but during a few years have elapsed since the discovery of the thing to do, we may reasonably hope for its much greater development in the near future.

EMPLOYMENT ARISING OUT OF THE VARIOUS USES OF ELECTRICITY.

There are many indirect methods in which labour is employed, indirectly, has been utilised, that do not admit of being ranked under any special head of its operations. Wire-drawers, and, in some cases, iron works, and copper smelting works, also copper casters, are largely engaged in the production of materials for the manufacture of electric signals. Timber dealers and their workmen, insulator makers and their employees, brass workers, spelter workers, engine builders, boiler makers, glass blowers, carbon plate and battery makers, and very numerous other occupations, receive considerable employment by means of the demands that electricity has created, but as the firms engaged do not generally devote themselves to meeting such demands, but exist also for wholly distinct purposes, it is impossible to arrive at any idea of the amount of labour actually required that they employ. It is equally impossible to estimate all the persons engaged in absolutely electrical trades. In Scotland there are 172 electro-plating and electro-gilding manufacturers, employing in all about 5,000 hands, and in Birmingham there are 99 manufacturers of the same class, two of whom employ 300 persons each, and others a large, though uncertain number in the aggregate. It may be certain, it may in the total be very large.

Decorative painters, electro-typists, and the like are so widely spread that it is impossible to collect reliable figures for them—the instances proving in that suffice—a similar conclusion to the former is only reached. It is the more difficult to arrive at any satisfactory determination because it is simply impossible to ascertain how many persons were employed in dealing with the old methods of working a time limitation.

In London alone there are, according to the "Post Office Directory" for 1888, 535 commercial firms, of greater or less magnitude, engaged in various operations of which electricity is the main agency. Some of these firms appear under several trade descriptions, and it is impracticable to assign any reliable figure to the number of their employees, for it is not to be very considerable. Each employer, although engaged in probably several distinct branches of trade, must engage one or more persons, in most cases, in each distinct branch. London employers must be added the numerous others existing in the great towns. I have, however, obtained reliable figures where possible. I will first take the case of the British Island.

The English Post Office employs, solely in the conduct of telegraphic operations, 16,303 persons. These individuals give us their services in connection with the electric telegraphs; many of them, however, are partially employed in the same work, but they do many other duties also, and possibly would be required for those duties did not the telegraph exist. I have, therefore, not included them as among those who have found their means of subsistence through the operations of electricity.

To this ascertained number must be added those who are employed by the various railway companies, either in the conduct of their general telegraphic business between station and station, in special duties in connection with the signalling of trains, or in upholding the telegraph lines existing on the different railways. I can, not, in the time available, get the figures I wanted from every railway company. I therefore contented myself with those of four great companies, whose entire systems extend over a length of 5,681 miles. I found that they employed 1,627 persons solely on telegraph work, and, as the entire mileage of railways existing in 1887, as given in "Bradshaw's" hand book, was 19,339 miles, I apply the rule of proportion, with the result that I find the total number of railway servants wholly engaged in electrical work to be 5,383. Many of the railways which go the make up the gross total mileage are small concerns, many are large ones, but as the infinite subdivision of lines multiplies the number of persons employed in carrying out the operations of any branch of work, I do not think that I can be far wrong in applying the ascertained results of the figures I have reliably obtained to the average of the whole railway system.

But like the Post Office, the railway companies have a very great number of persons partially, though not wholly engaged in similar operations. The men at the numerous signal cabins not only work the levers controlling the fixed signals, but usually manipulate the block telegraph levers. At many small stations, where there is but a limited force engaged for the discharge of all duties, the booking clerk works the instrument in addition to his other employments. I do not count either of these classes among the purely electrical employees.

The Exchange Telegraph Company, a licensee of the Post Office, engaged mainly in the supply of intelligence of special events to clubs, public institutions, and private persons, employs the entire time of 182 persons, besides the partial time of many others who supply the company with reports and information.

Thus the number of individuals engaged entirely in the transmission of business brought about by the existence of the electric telegraph in Great Britain and Ireland is as nearly as I can ascertain, 23,868 persons, to which must be added an army of persons who probably find their incomes more or less considerably increased by the same cause, though not entirely dependent upon it.

I intended to continue myself to the economical figures of the British Islands only, but I may remark that if the rule of proportion holds good in this branch of the subject, and the entire mileage of public telegraph wires of all kinds in this country be, as is the case, 223,000 miles or thereabouts, while those of the world approximately amount to 1,800,000—omitting submarine cables—we have, as in the case of 23,868 persons are employed, a total number of 179,748 persons who find a field of labour in the working of telegraphic communication throughout the globe. It is impossible, seeing the varied circumstances existing in different countries—in some there are long mileages of wire connecting comparatively few offices or stations, in others there are short mileages connecting many stations—to say that this total is correctly arrived at, but it cannot fail to be at least an approximation to the truth. In some countries the available figures are indefinite as regards the differences between Governmental lines and those for railway purposes; in some, telephone lines are mixed up with the figures for telegraph lines. Thus the totals I have given are liable to error, but it is, at any rate, error on the right side and the number of individuals engaged in their working in all probability will rather exceed than fall short of the numbers I have given. The facts as to the partial employment of individuals not enumerated as telegraphic employees is common to all the world, and not by any means limited to the United Kingdom. To the known and fully occupied a very large addition must be made to represent the unknown and partially occupied.

The Submarine Telegraph Cable Companies must next be considered. From three of these—the Eastern, the Anglo-American, and the Submarine—I have obtained the actual figures. Their employees number in all 2,168. These three companies possess about 36,697 miles of wire, and throughout the globe there are about 107,000 miles of cable wire. Discharging those cables that are really integral portions of land circuits and which have no separate organisation, the persons employed in working them are treated as if engaged on land telegraphs. By proportion, this total mileage of wire in cables should make the entire number of persons employed, 6,315. Some time ago the Eastern Telegraph Company endeavoured to get up a census of the number of persons employed in submarine working throughout the world, and arrived at a total of 4,844 persons, but I am not certain that all the lines included in the above calculation were existing at the time such census was compiled. I am pretty sure they were not. I take the actual total of persons employed at 6,000.

These cable companies employ also cable ships in repairing and maintaining the submarine lines. Of these I speak more fully when dealing with cable manufacturing companies.

Next in order come the telephone companies. These, in proportion to the number of their wires, of course employ comparatively few persons, as the centers of the lines are their own manipulators; they employ attendants only at exchange switches, but nevertheless the information received from all the companies existing in Great Britain and the North of Ireland shows that their operations give employment to 2,386 persons. To this number must be added that of the company working in Dublin and the south of Ireland, thus the total is raised to certainly 2,500 individuals, probably more. I say no facts upon which I can extend the comparison to the world generally, but seeing the universal adoption of this means of communication, and the extent of its development in the United States especially, there can be little doubt that the aggregate total of persons engaged in carrying out this form of electrical undertaking must at least reach 30,000.

The electric lighting industry then comes under consideration. From five of the largest concerns engaged in the business of either providing apparatus and mechanism for its production, or obtaining such means for the actual installation of the illuminant, I have re-

derived out of the average number of their employees. These amount to 1,828. The five companies supplied, although much the largest by no means represent the greatest extent of the entire electric supply employed in the like manner. I assume that these five or six companies, taken in putting down at least 5,000 as the ratio for our own country, and keeping in mind the fact that all countries well equipped, except the new light, some to an extent much exceeding so, and it is reasonably certain that twenty times this number as 100,000 will not be too great a figure to represent the entire strength of the workers in this field. Along with the electric light companies and the employment they give, I comprise those of the makers and producers of every article or apparatus mainly occupied in operations auxiliary to the production of the light.

There remains to be considered the number of persons employed by the submarine cable and land cable telegraph companies who most of them make alterations in the instruments used in telegraph working and in other electrical applications. The extent of the employment given by these varies considerably as, of course, cable working is a somewhat fatal industry the periods of a year and a half, and of comparative slackness alternate with each other. Even the three largest companies in the Kingdom, I learn that the average number of persons employed by them varies from 5,457 at a maximum to 1,303 at a minimum. This gives an average of 3,630. The trade, so to speak, is more concentrated than in the case of the electric light and it is probable that about 5,000 persons will be a fair allowance for the entire number engaged in it at any one time.

In the foregoing table, however, the number of persons actually employed in the cable-laying ships of the various manufacturing companies, as also the case with the repairing ships belonging to the different cable companies. The vessels represent a kind of international fleet engaged solely in attendance upon the cables in which their waters are at stake. They are of all sizes, from the gigantic "Silverstream," "Famaly," and "Saxonia" to vessels of 300 tons and 400 tons burden. Our nearest neighbor therefore must be counted among the companies benefited by the advent of electricity.

We must not overlook the large body of persons engaged in teaching the aspirants to electrical knowledge. At universities, colleges, and technical schools a good much of science has been added to the previous curriculum. Professors, demonstrators, and their assistants are present in the schools a very important and serious class. The pupils in an appreciable number represent workers ranked in one or other of the occupations I have mentioned, while numerous others have as yet attached themselves to no special form of work but are expecting to take part in some definite sphere of labour when their studies are sufficiently advanced. It is amongst these, regularly trained for the conflict that we must look for our future victories, for the most forces of nature. It is they who will advance that which is yet struggling with the difficulties that surround the unknown. It is to them that we must look for future discoveries which will make the plain and easy which now has to be sought for through much trial and many errors. In the early days not grouped in the dark towards the light, as it were, but our present students of electricity have at their disposal a clear source of light, the harvest of the past to aid them as a torch on their way to fresh operations in the same field.

Finally must be mentioned the technical press. Independently of the papers devoted mainly to other interests, such as *The Engineer*, *Electrician*, and then, like other papers, a special one devoted to electrical science we have in *England*, *America*, *France*, and *Germany* alone between twenty and thirty organs interested wholly or specially in the publication of facts and opinions on every branch of electricity. This department of the press is invaluable in requiring a special knowledge of what is going on by various workers in the electrical field throughout the globe, and is itself a literary outgrowth of the new vigorous spirit we are regarding.

Considering the foregoing figures, the results come out as follows:—

Employed in connection with	Number of persons	Probable number of persons employed throughout the world.
British and telegraphs	25,368	180,000
Submarine cable companies		
mainly British	6,000	
Telephone companies	2,500	30,000
Electric lighting	5,000	100,000
Cable-making, and allied businesses	5,000	
	42,368	

Add to these the individuals that cannot be classified who must amount in the aggregate to at least an equal number. We arrive at a total approaching 100,000, in round numbers, of persons dependent for their employment on the various operations directly connected with electricity in these islands alone. Besides a very large addition to the output of various trades caused by its consumption of the industries they produce. The employment of 100,000 persons means the support of at least 500,000 of the community. An immensely large proportion of young or at least unmarried people of both sexes minister to the calls of electrical work, and hence I take the average family at three instead of the usual calculation of four and a half or five.

If these figures represent even more, as I think they do, it is evident that throughout the earth there must be 5,000,000 of people, at least, who would have to seek for other means of subsistence if electricity and its numerous applications had not been made known to man. Thus it is evident that a very blessing has been conferred by the discovery of its potent force—a blessing to the whole of the world at large—who profit by its operations, and a further blessing to the whole of mankind whose to it, it alone has in carrying them out. How great will be the statistics similarly occupied and similarly dependent when a century more has rolled away!

Thus far I have sought to sketch, although briefly and imperfectly,

the various modes in which electricity is utilized, and to arrive at some idea of the extent of employment derived by the workers who strive to secure such utilization. But this is at best an approximation to the truth at this present moment. It is little more than fifty years since the powers of the new agent were first turned to practical account, and I think that time the world has been one of confusion and unaided progress. Discovery has succeeded discovery, and invention has followed upon invention. At present many fields are entered upon, but scarcely trodden. Electric motors and their like have hardly an unknown, or unimpassioned light before them. What is to come is as nothing to what will be done. The fusion of the influences of sound and light, the laws of heat in relation to the power which is generating, and its equally important bearing upon those of statistics open up so many questions in which we may look for future researches to make good that now shows, as it were through a glass darkly, clear and distinct if not to ourselves at least to future generations. The London and the industrial and agricultural as the present time between the two they are separated and the everstriving lightning discharge from the clouds. Large quantities of electricity are already controlled and limitations of the same agent have been discovered, but in their endeavor to control they change greatly the sphere of its uses.

As a student, watching the progress that has been made, and is still making by the earnest workers who have given to the world so much, tracking the influence between the knowledge of the present day and that of the past, which existed over thirty-six years ago, when I first knew the difference between a battery and an accumulator, and conceived some vague idea of their respective limitations. I am struck with astonishment. In 1852 the *Ramden* had been crossed, the dynamo had given place to the practical work, but as yet the latter had not advanced very far from the basis laid down by his predecessors, the spirit of the original was as yet the controlling influence, not the mind of the student was set free, and each master showed the results of unshaken energy. Now he is unshaken of them, have been opened new applications have been discovered, in which the power of electricity have been, of late, new applications have been greatly advanced and extended. In the time of which I speak comparatively few of the agencies in telegraph working, and that was speaking broadly, the old demonstrations of electricity that could be explained only in terms of attraction and repulsion by any knowledge of the science upon which it was founded or interest in the progress of might make, I trust looked to it as something in the operation of which the common contrivance with point to themselves, something ignorant of the laws that governed it, or the reasons why certain apparatus was employed to produce its effects. To them any knowledge they might glean was—partial, the pure result of experience in a practical form. At the present day an entire change has taken place. Into courses of the advanced operations of electricity does a youth engage himself without having some taste or liking for investigation, and the acquirement of real knowledge of the subject in which he is interested. Sometimes such as this best justify their existence in finding aid to those who seek to devote themselves and to know what can be carried from their predecessors it learned laborers.

A distinguished scientific statesman once described the mere workers of electric telegraph systems as "multiplexers, mixers, they know only that carrying a certain bundle to the right or to the left, or a key to a wire down, produce signals or marks that are legible at the first end of a wire, but how they produce them, or how they were originally given, it is not so with the student of modern days. The man who devotes his life to the electric light, motive power, or other allied branches, knows that he must pursue himself by a good course of the original study before he undertakes practical work. He must know the reasons for all that he does.

Thus it is clear to me that in the facts I detailed was the strongest indication of the progress, education in the new of our society. In the summary of electrical operations which I have put before you I have given the largest space to the electric telegraph and its results. I have persisted in so doing, because the telegraph is the most nearly completed of all the branches, it cannot the laws of electricity are discovered. No doubt there is still room to improve its processes, but it, however work is done, and it is scarcely possible to find the future can yield more than progress, however important in details. When the Society was first founded "Telegraph Engineers" was a fitting name, as it was only in telegraph engineering that any considerable number of the followers of the science we are considering were actively engaged. A great change has taken place, positively even more important than that was then, this new activity has so. The truth has been so much felt that it offers little temptation to the average glimmer. Speaking generally men's thoughts are directed to other channels, where they may seek, in partially explored or unknown regions, the fame and profit that may accrue to those who win victories there. "Telegraph Engineers" are still the most numerous units in our body, but from the force of circumstances they are no longer to be the spearhead, the vanguard, the leader. The Institution of "Electrical Engineers" is a title comprehensive enough to include all devotees of the science, no class of workers is singled out for undue prominence, no class is by implication excluded.

The President of the Royal Society, in his recent address, told the members of that learned body that the world wanted a great discovery—that it was most desirable that the nature of electricity should be made known and used. We may be or may not of such a discovery, we may be far from it. The problem to be solved, that of the transmission of the system as agent that seems to pervade all nature, ranks apparently with the equally puzzling one, "What is the soul?" Philosophers and the logical students have quarrelled over the latter question for many generations without advancing nearer to a solution. Let it be said that "What is electricity?" may, in the fulness of time, receive an answer which will extend the boundaries of its use to purposes as yet undreamed of, and that the benefits it confers upon man may be thereby multiplied many fold.

CITY NOTES.

German Union Trust.—The directors have declared an interim dividend of 5s. 9d. per share.

Eastern Extension Company.—The interest of this company's Six per Cent. Debentures, due February 1, will be paid at the Consolidated Bank, 52, Threadneedle-street, E.C. Coupons must be left three clear days for examination.

Direct United States Cable Company.—The report of the Direct United States Cable Company for the six months ended the 31st December states that the revenue (subject to revision on settlement with the French Company), after deducting out-payments, amounted to £23,003, against £19,603 (after similar deductions) for the corresponding period of 1886. The working and other expenses, including income-tax, &c., amounted to £15,865, leaving a balance of £7,138 as the net profit, making, with £5,004 transferred from the

reserve fund account, a total of £12,142. For the corresponding half-year of 1886 the working expenses and other payments amounted to £16,354. Interim dividends of 2s. per share each for the quarters ended the 30th September and the 31st December, together amounting to £12,142, have been declared.

Eastern Telegraph Company.—The directors of the Eastern Telegraph Company (Limited) in their report for the half-year ending the 30th of September state that the revenue amounted to £291,265, from which are deducted £79,936 for the ordinary expenses and £34,102 for expenditure relating to repairs and renewals of cables, &c. After providing for income-tax, there remains a balance of £172,761, to which is added £559 brought forward. From the available balance there have been paid—Interest on debentures and debenture stock, £28,538; dividend on preference shares, £20,384; and two interim dividends of 1 1/2 per cent. each on the ordinary shares, £95,000, leaving £29,398 to be carried forward. The directors have satisfactorily completed the issue of 4 per cent. mortgage debenture stock to replace the £450,000 5 per cent. debentures which fell due on August 1st last.—The ordinary meeting was held yesterday.

NOTES.

Subaqueous Illuminations. In the experiments made at New York with a submerged 100-candle mean descence lamp, objects at a distance of 148ft. from the lamp were, it is said, rendered visible.

North Shields. The covered market for North Shields was opened last week by the Mayor of Tynemouth. This market is another example of modern innovation, it being lit by means of the electric light.

Lighting of Messrs. W. H. Smith and Son's.—We understand that Messrs. Woodhouse and Rawson have been entrusted with the wiring of Messrs. W. H. Smith and Son's extensive premises in the Strand, in order that the offices may be lighted by electricity.

Torquay. We are glad to see that the use of the electric light is extending to provincial theatres. At the Torquay Theatre the flies of the stage are lighted by electricity, and this method of illumination is utilised in some of the spectacular scenes of a play now running.

Amiens.—The Société Industrielle of Amiens offers a prize for the best electric light installation in a factory. The installation must be equivalent to 300 gas jets, and cheaper than gas made on the premises. The plans and description of the installation must be sent in to the Society before the last day of April.

Copper. The Paris correspondent of the *Times* has given his explanation about the present copper "boom." It arose, according to this account, from a speculation of the Société des Métaux, which, finding itself and friends loaded with a large amount of Rio Tinto shares, was compelled to go on buying and bargaining.

Solution for the Electro-deposition of Aluminium.—According to the recipe of M. Hermann hemond, 50 parts by weight of alum (ammonia alum) are dissolved in 300 parts of water, 10 parts of aluminic chloride are then added, and the solution is heated to 212° Fah. After cooling, 39 parts of potassic cyanide are added. A plate of aluminium constitutes the anode, and the current employed must be weak.

Electro-deposition of Metals by means of the Disruptive Discharge. Mr. R. K. Boyte, according to the *Scientific American*, has devised a process for coating objects with a layer of any given metal by a dry method of electro-deposition. The object to be coated is covered with a sheet of the metal which is to furnish the deposit, and an intermittent discharge it is not stated from what source nor in which direction is passed between them.

Oidium Medicum.—Dr. T. Wilson, taking part in this controversy, which has been lately raging in *The Times*, asks, as part of his argument: Who can explain why a powerful horseshoe magnet can magnetise a bar of steel and lose its power, in fact improve by the operation? One may continue to magnetise steel with the same horseshoe magnet for ever and ever, until all the steel in the world becomes magnetic, and still the magnet remains as lively as ever.

High Jinks.—At a conversazione and concert, held at the Edison and Swan Company's works, Ponders End, nearly the whole of the employees accepted the invitation of the manager, Mr. Cunningham, to whose kindness the entertainment was due. The musical section of the employees volunteered their services, and a pleasing programme was

provided, the performances being much appreciated. The entire arrangements were carried out in a highly satisfactory manner.

Watt-hours or Watts-hour. We notice that some of our esteemed *amis* *doutre Manche* employ, as the plural of *watt heure*, the expression *watts heure*. Surely this is a mistake. The unit of work in question, in the plural, might just as well be hour-watts as the converse. It is the compound word that is in the plural, not either of its components. The expression we refer to would convey the impression that the numerical value was dependent upon, and equal to, the number of watts only—the unit of time being taken in the singular.

Conical Electro-Magnets.—In the case of a cylindrical electro-magnet, the magnetic attraction becomes nil at a distance from the pole greater than half the length of the magnet. But if the core and its surrounding coil are of conical form, the distance of attraction, measured from the smaller end of the core, may extend to two-thirds the length of the magnet. According to *l'Electricien*, M. Th. Burger, who has recently taken out a patent in Germany for electro magnets of this form, recommends the use of a double magnet, i.e. two conical magnets, one fitted within the other, and having their similar poles at the same end.

New Carbons for Arc Lamps.—Mr. Gime has devised a new process of preparing carbons for arc lamps, which it is said gave good results. These carbons are made as follows: Equal parts of close burning coal and very pure coke are triturated together, and to them is added a sufficient quantity of water saturated with boric acid to make a plastic paste, which latter is passed through moulds under a pressure of from 75 to 100 atmospheres. The rods obtained are cut to the proper length, put into a furnace, and raised to a bright red heat. A single baking produces very dense and hard carbons.

Electric Traction.—According to the *Telegraph*, the Metropolitan Railway Company have concluded an arrangement with the Electric Traction Company for the experimental running upon a section of the line outside the circle of an electric locomotive of the same power as the present steam locomotive. The Traction Company stipulate that should the experiment prove an advantageous and economical method of working they are to have the option of entering into an agreement for working the railway by electricity for a term of five years, at a rate per train mile to be agreed upon, such rate not to be in excess of the cost of working by means of steam locomotives.

Soldering Telegraph and other Conducting Wires. With a view to save expenditure of time in cleaning the rusty ends of wires to be soldered together, Mr. Prinsjuský, in an American contemporary, makes a suggestion which strikes us as not being altogether novel on this side of the Atlantic. A quantity of solder is melted in an iron pot, and fragments of sal ammoniac, which become melted, are thrown upon it. The ends of the wires are first dipped into the fused salt (which has the property of dissolving most of the metallic oxides), and afterwards into the solder, being in the latter case held together by binding wire or other suitable means. Should the solder not adhere on the first trial, the operation is to be repeated.

Electric Lighting in the City.—At a meeting of the City Commissioners of Sewers on Tuesday, Mr. J. S. Bell brought up the report of the Streets Committee, which contained an amended arrangement with the Anglo-

American Brush Electric Light Corporation for lighting a district of the City by electricity. Mr. Bell said he was sorry to see that so many of the members had left the court when a question of such importance was to be considered.—Mr. Shaw thought the subject was far too important to be settled at the far end of the meeting, when many members who desired to take part in the discussion had left. Ultimately it was agreed that the matter of the report be printed and circulated among the members, and that it should be considered at an early hour at the next meeting of the court.

Madrid.—Fourteen petitions have been presented to the municipality of Madrid to use the public thoroughfares for laying cables for the supply of electric light and power; but, in the unbusiness-like manner in which such things are dealt with by the local authority, no decision has been come to, and it is difficult to say when there will be one. In the meantime a very badly managed company, who have a provisional authority to lay cables, is supplying about 1,000 incandescent lights and some 80 arcs. On the other hand, the Madrid Gas Company pretend that they alone have the right to lay underground cables for electric light. In fact, everything relating to distribution is in such a state of chaos that even primary batteries would have a chance of adoption if their working expenses could be brought down to a point at which the cost would be about equal to 8s. per 1,000ft. for gas.

The Proposed Pacific Cable.—A special dispatch from Ottawa, Ontario, to the *Boston Herald*, under date of December 27, read as follows:—Your correspondent learned at the Department of Marine and Fisheries to-day that, owing to some misunderstanding between the Dominion and Australian Governments, the departure of the Dominion Government steamer "Alert," which was to have left Halifax this month for the Pacific, to make a survey from British Columbia to Australia, for the proposed cable, has been indefinitely postponed. The two Governments were to carry on the survey jointly, the Dominion Government to furnish the steamer and Australia to defray expenses. Every arrangement had been made for the "Alert's" departure, and the delay has caused much disappointment to the projectors. The cable was to form part of the Fleming system, by which he proposed to connect British Columbia, Australia, and India, and in which he has been promised the support of all the Governments concerned.

Telephone Switch Board.—The largest of these boards at present existing is at the New York Exchange. This board is subdivided into 44 sections, and is placed on the top floor of the building. It will accommodate 6,000 wires, with capacity for increasing to 10,000 when wanted. This mammoth board will be nearly 300ft. long, running through each wing of the building, and across the front. To make the connections in the office, over 1,000,000 joints had to be soldered in the wires, and about 3,000 miles of wire have been used. There will be an operator for each 50 subscribers, and each operator will be provided with the most advanced improvements in telephone transmitters and head receivers. The batteries are all under the floor of the room, where they can be readily reached, to ensure proper care, and every other possible provision has been made to secure as nearly a model service as can be obtained at this time. Some idea of the tremendous size of the board may be gathered when it is stated that 110 men were constantly employed for two months, and a large number for several months, in the construction of it.

Overhead Wires in London.—The opposition of the local authorities to overhead wires in and around London, which in 1885 led to the withdrawal of the bill introduced by the United Telephone Company, is likely to be renewed this session through the depositing of a bill by the same company to carry out in a more limited area the powers originally proposed in 1885. The main object of the bill is to obtain Parliamentary sanction to the erection of overhead telephonic wires along any road or land within the city of London, the county of Middlesex, and so much of the counties of Surrey, Kent, and Herts, as lie within 12 miles of the General Post Office. For this purpose powers are sought to place and maintain posts along any roadway upon giving 21 days' notice to the local authorities; and over any lands, with the consent of the occupier, lessee, or owner. By the bill of 1885, it was intended that these powers should extend to 100 miles of the General Post Office, instead of 12 as now proposed. These powers are asked for, we suppose, in order to enable trunk lines to be erected, to connect London with other industrial centres.

Primary Batteries.—Mr. C. R. Alder Wright has made experiments in the construction of batteries in which platinum or carbon plates are immersed in communicating fluids capable of undergoing chemical reaction. In all cases the plate immersed in the oxidisable fluid acquires the lower potential, the other the higher potential. The liquids are prevented from mixing by the interposition of some other liquid, through which the two must diffuse, the intermediate reagent being placed in the bend of a U-tube, the limbs of which contain the other two, or in a beaker placed between two beakers containing the others, and communicating with them by cotton or asbestos wicks. Among the liquids mentioned are:—(A) Solution of sulphurous acid opposed to potassium chromate and sulphuric acid solution, with sulphuric acid intermediate; this cell develops about 1.5 volt, and is constant. (B) Sodium sulphite solution opposed to potassium permanganate rendered alkaline with potassium hydroxide. (C) Chromium sesquioxide dissolved in sodium hydroxide, opposed to potassium bichromate and sulphuric acid solution. (D) Potassium ferrocyanide opposed to potassium bichromate and sulphuric acid. (E) Lead oxide dissolved in sodium hydroxide, opposed to alkaline permanganate, hypochlorite or hypobromite.

"Toy Telephones."—Two amusing stipulations were filed in the United States Circuit Court yesterday by the defendants in the case of the American Bell Telephone Company against A. S. Aloe and others. Last August the Bell Telephone Company commenced a legal war on all parties having in their possession, making, selling, buying, or using electrical apparatus similar to those made and used by that company, and for which it had letters patent. In answer to the charge Mr. Aloe said he acknowledged the letters patent and had made no attempt to infringe. While in Paris a few years ago he bought three toy telephones, which he afterwards used in his store. He sold a set of them to a party unknown to him, not knowing that the same was an infringement. He destroyed his set of toy telephones as soon as he heard he was infringing, and promises not to make or sell any more. He asks that the case be dismissed at his cost. As to William Grady, his chief clerk, charged with in the case, he says he reprimanded him and told him not to abuse his position. Mr. William Grady, the "et al" in the case,

says he admits the validity of the patents and did not use any other than the Pan telephone, and he promises not to use, make, sell, buy or procure any telephone but the Bell. This statement, he concludes, is made voluntarily, at the request of the Bell Telephone Company. —*St. Louis Republican*

Testing Dynamos.—M. Hummel, in the *Electrotechnische Zeitschrift*, suggested a modification of Cardew's plan of testing dynamos, the following abstract of which is from the *Institution of Civil Engineers' Journal*: "In certain cases the approximate total efficiency of two dynamos can be readily determined by Cardew's method, which is, however, inapplicable to the testing of a single machine. With the author's arrangement the energy absorbed by any given machine is deduced from the electrical measurements of a dynamo, which may be called the standard machine, or D_1 . The output of this standard, with any definite current strength and potential that may be decided upon, and at a certain number of revolutions, is obtained beforehand by means of a brake. The measurements were made in two series. In the first, the current strength was maintained constant, whilst the speed and potential varied within wide limits; in the second, the speed was kept uniform, and the current and potential altered. The load on the brake during each test was changed according to the output. Curves representing the results obtained were plotted out, so that the amount of mechanical work available at the axle of the standard dynamo is at once known, or can be readily computed by means of a simple interpolation whenever the current strength, potential and number of revolutions of the machine are at hand. This graphical representation of the working conditions of D_1 has also been utilised to determine the energy absorbed by various experimental machines, shifting, gearing, &c., as well as the loss due to currents in different rings for Schuckert's machines, and in armature discs, &c."

Electric Telegraph in China. A feat in the suspension of telegraph wires, says the *Engineer*, has just been accomplished in the Celestial Empire, which, we believe, has been surpassed but in a single instance only. The river Yang, in the province of Chih Li of that country, had to be crossed. This river when at flood is ten miles broad; but it is at all times a wide and rapid stream, running between precipitous banks. The cables at first laid down were completely destroyed by the force of the stream, and it was found impossible to establish communication by their means. A *détour* of twenty miles discovered a possible crossing place for aerial wires. A cable of steel wire was specially made by Messrs. Siemens, of London, composed of seven strands, each 0.115 in. in diameter. This cable weighed 6½ tons, and had a breaking strain of 15,000 lb. To reach its destination it had to be carried in carts over 130 miles of very rough and mountainous country. When erected its horizontal span was 4,648 ft., the height of the two supports being 447 ft. and 737 ft. respectively above the river bed. As it now hangs, the vertex of the curve of suspension is 78 ft. above water level. The work of erection has been carried out by Mr. A. de Linde, a Danish engineer, under the direction of Mr. C. Poulsen, assistant director of the Chinese Government telegraphs. The sole instance of a greater existing span referred to above is one over the River Kistna at Bezarrab, in the Madras Presidency, the span of which is 5,070 ft. The work of telegraph extension in China, after it leaves the vast alluvial plains of that country, is evidently one involving the exercise of high engineering skill.

An Electric Birch.—"The latest advance in applied science hails," says the *Private Schoolmaster*, "from La Belle France. A French schoolmaster has freed himself from the trammels of conventionalism, and added a new chapter to the history of flagellation by inventing an electric birch. Electric birch, forsooth! We have heard of many strange things that have come out of electricity, but anything so scientifically illustrative of the *argumentum ad hominem* or *ad baculum* we have, indeed, never heard of before. There are, however, two properties of this electric birch that do not belong to the bundle of birchen twigs, heretofore orthodox; and in themselves they have certain claims to superiority. By the employment of electric punishment, no mark or sign is left upon the skin, to the disgrace of the boy whose schoolfellows may know of such a souvenir of a *unanimis quart d'heure*, or to his discomfort should he desire to sit down. Again, by the use of easily adjusted machinery, the force of the blows can be regulated to a nicety throughout their infliction. This is a boon to the boy, for it is a protection from the master, who may be a bad tempered man, and warm to his work as he proceeds. But we fear that the ingenious pedagogue who devised this electric birch is not destined to realise a fortune by his invention. Were we once to accede to the offers, however liberal, that science may make us in the matter of flagellants, there would loom before us a whole machinery of terror, in comparison with which the racks and screws of the Inquisition and the formidable fuses of the Roman lictors would pale."

Electrical Distribution of Time.—Many attempts have been made in past years to solve the problem of causing the pendulums of different clocks to vibrate in unison with each other by means of an electrical current periodically transmitted from a central station; but hitherto inventors have not succeeded in obtaining perfect synchronism. In a paper recently read before the Paris Académie des Sciences, M. Cornu has returned to the subject and shown analytically that to obtain synchronism in a vibrating system, the necessary and sufficient condition is that the free motion of the system shall be a damped vibration, and has also pointed out that the stable condition is obtained more rapidly the greater the amount of the damping. To carry out this in practice, it is necessary, if two pendulums are to vibrate, that they should synchronously experience an impulse in one direction, and a retardation in the opposite sense in rigorously the same way. This M. Cornu obtains by fixing a permanent magnet to the lower extremity of the pendulum, the magnetic axis being perpendicular to the axis of the pendulum. An electro-magnet, with an open circuit, is fixed on one side of the pendulum and attracts it at each oscillation. On the other side is placed another electro-magnet, with a closed circuit, which acts simply as a damper and checks each swing. In this way perfect synchronism can be obtained between clocks a very considerable distance apart, which, indeed, is only limited by the length of line at which the retardation of the current from self induction becomes sensible. Clocks constructed on this principle for the Geographical Department of the French War Office have been successfully synchronised over a distance of forty miles of a defective telegraph line.—*Engineer* (copy).

Dangers of Overhead Electric Wires.—In New York recently people passing along the east side of Union Square about nine o'clock in the evening were attracted to a small but brilliant pyrotechnic display made by one of the telephone wires crossing Fourth Avenue at Fourteenth

Street. Suddenly a spark larger and more brilliant than any of the others flew from the wire, and a team of horses drawing car No. 137 of the Fourth Avenue line, which was passing under the wire at the time on the uptown track, began to dance and prance about. One of the horses the next moment dropped to the pavement as though it had been shot, and the driver noticed that the thin telephone wire was broken and wound round the animal's legs and neck. He jumped from the car and was about to tear the wire from his horse's neck, when Officer Kaeser, who happened to see the occurrence, held him back. It was then discovered that the horse which had fallen was dead, and the deadly character in the broken wire thus being demonstrated, there was a lively scattering of the crowd in all directions. Officers Kaeser and Hass succeeded in taking the harness from the live horse, and saved it from the fate of its mate. Travel was delayed on the Fourth Avenue line for over a half hour. Finally a man came along with a ladder, and a huge pair of rubber gloves on his hands. He climbed the ladder, which the policeman held as far from the dead horse as possible, and cut the wires. The circuit was thus broken and the danger removed. The horse was quickly hauled from the track and travel resumed. The accident was caused by the telephone wire falling upon the electric light wire, and becoming impregnated with the strong current of the latter.—*Scientific American*.

Pepys' Electric Furnace. Prof. Houston, writing in the *Journal* of the Franklin Institute, points out that the idea of utilising powerful electric currents for performing such metallurgical operations as require a high and yet readily regulable temperature is quite old. He purposes giving brief descriptions of the early applications of electricity to furnace operations, and goes on to describe the work of Pepys which was connected with and directed to the establishing the identity of the diamond and carbon. The apparatus devised for the purpose constitutes one of the earliest electric furnaces. Mr. Pepys bent a wire of pure soft iron, so as to form an angle in the middle, in which part he divided it longitudinally by a fine saw. In the opening so formed he placed diamond powder, securing it in its situation by two finer wires laid above and below it, and kept from shifting by another small wire bound firmly and closely around them. All the wires were of pure soft iron, and the part containing the diamond powder was enveloped by thin leaves of talc. Thus arranged the apparatus was placed in the electrical circuit, where it soon became red hot and was kept so for six minutes. The ignition was so far from intense that few who witnessed the experiment expected any decided result. On opening the wire, however, Mr. Pepys found that the whole of the diamond had disappeared; the interior surface of the iron had fused into numerous cavities, notwithstanding the very moderate heat to which it had been exposed, and all that part which had been in contact with the diamond was converted into perfect blistered steel—a portion of it being heated red, and plunged into water, became so hard as to resist the file and to scratch glass. As will be seen the above is an excellent description of an electric furnace pure and simple. Bearing in mind the date of the publication it shows very considerable ingenuity.

"Journal of Gas Lighting."—Perhaps one of the most wonderful operations in modern scientific literature has been the compulsory acknowledgement of the *Journal of Gas Lighting* that there was any future for electric lighting. In the current issue, after dealing with our criticism on

the *Morning Post*, our contemporary concludes its usual weekly article with the following paragraph: "There is an electric lighting installation at Kensington Court, which at the present time supplies about 1,000 incandescent lamps in private houses in the neighbourhood of Kensington and Chelsea. This venture is under the control of Messrs. Crompton and Co., who anticipate a large increase of business in the locality, and say they have room at the station for plant to supply 20,000 lamps. The charge is after the rate of 0.28d. per hour per lamp, or 8d. per Board of Trade unit, or 6s. 8d. per 1,000 cubic feet for equivalent gas lighting, which does not appear to frighten the dwellers in this well-to-do neighbourhood. It seems probable that the year will witness a decided extension of these small lighting stations in the City of London and some of the richer suburbs. The idea in favour for the moment is for the owner of a large house or suite of offices to put down larger generating plant than he needs for his own premises (which does not greatly increase his capital outlay), and then to supply a select coterie of neighbours. This arrangement pleases both parties, presuming that they like electric lighting. It causes no more work to look after a 2,000-light plant than after one of half the power; and the rental to the outside consumers can be fixed at a price to return a little profit to the man who has the trouble of the machinery. The insurance offices are in possession of a number of proposals of this character, and have not quite settled what rate to charge for the extra risk. It is, of course, easy to exaggerate the significance of this movement. But there can be no doubt of its reality; and it must be noted as one of the signs of the times."

Sunstroke by Electricity. Dr. Defontaine, the medical officer attached to the famous French foundry at Creuzot, recently communicated to the Surgical Society of Paris some observations on sun-stroke by electricity. The phrase seems a misnomer, but none the less what Dr. Defontaine describes seem to be veritable cases of sunstroke. At Creuzot, electricity is employed in the form of an intense focus to smelt certain minerals, as well as to melt and solder metals. A metal placed in the electric arc is fused as if by magic, steel melting in a few seconds. The electric arc in which metals are soldered is of marvellous radiance, its luminosity focussed upon a few square inches exceeding 10,000 candle lamps and surpassing 100,000 candles. Although persons standing near this glow feel no heat they become conscious of acute pain, and for an hour or two afterwards those who have been within ten yards of this intense radiance experience a burning sensation, with more or less pain in the neck, face, and forehead, their skin at the same time assuming a coppery red tint. Although it is customary to protect spectators' eyes with blackened sun-glasses, the retina is affected to such an extent that blindness supervenes in broad daylight for several minutes, and for nearly an hour all objects are seen in a deep saffron colour. There is irritation of the conjunctiva, and the congestion lasts 48 hours at least, accompanied by a sense of gritty particles inside the eyelids. The lachrymal glands suffer excessive stimulation and tears flow, while other symptoms are sleeplessness and headache. In ordinary sunstroke it is customary to attribute the illness produced to the heat, because in that case the solar heat is felt. But in the case of electricity there is no heightened temperature, a thermometer placed within five yards of the electric arc that is melting steel like butter scarcely being affected, so intensely is the heat concentrated. But while the thermometer is unaffected by close contiguity, persons standing

fourteen yards away suffer from stroke, proving very conclusively that it is the light and not the heat which is the cause of the mischief.

Vienna.—The Vienna Society of Electricians appointed some time ago a committee to draw up rules and regulations for the public supply of electricity, which will be submitted to Parliament with a view to obtain a kind of Electric Lighting Act for Austria. The committee have finished their labours, and their report will be laid before the members at the next general meeting of the Society. It will then be discussed, and, if necessary, amended, after which the Society will finally adopt and recommend it as the basis of a Bill to be introduced in the next session of Parliament. Messrs. Czeija and Nisch, of this town, have just brought out a new search light, which has been specially designed for use on torpedo boats. The lamp is self feeding and works perfectly well, not only when placed vertically, but even when inclined to an angle of 65 deg. from the vertical.

The Allgemeine Elektrizitäts Gesellschaft, of Berlin, is now establishing a branch at Vienna. The company has commenced negotiations with the Imperial Continental Gas Association, with a view to taking over their electric light works in the Schenkenstrasse, and the installation at the Vienna Opera House. This company will also be represented at the forthcoming Exhibition in the Prater by an installation of 90 arcs and 1,500 glow lamps, lighting the park to the west of the Rotunda, and a portion of the interior of the latter. The rest of the lighting will be divided between the following firms: Siemens & Halske, of Vienna; Egger & Co., Kremendky; Mayer & Co., Krzik; Ganz & Co., and Brueckner, Ross & Co., who will install an aggregate of 180 arcs and 2,000 glow lamps. As in 1883, a special feature of the exhibition will be model rooms furnished in various styles, and lighted by glow lamps, for which purpose about 750 lamps will be required. In the Emperor's pavilion there will be 100 glow lamps. Generally speaking the electric light will be installed not as an exhibit, but with a view to produce the best illumination of the other exhibits. The total motive power required is estimated at 600 h.p. There will be telephonic communication by means of Fostin Herrman underground cables between the Vienna Opera and the Rotunda. *Industries.*

Accumulators for Electric Light Installation.

We have to obtain the *constants* of the lamps in normal working: amperes, volts at the terminals, watts utilised in the lamps, the maximum number of lamps to be worked at the same time, and the total extent of the lighting to be directly effected by the accumulators, expressed in watt-hours. We will suppose, as an example, an installation of 20 lamps of 10 candles, each taking 1 ampere and 30 volts, or 30 watts. A maximum of 10 lamps is to be worked at the same time, and the daily amount of lighting is about 8 lamps during 5 hours, or 40 lamp hours, or $40 \times 30 = 1,200$ watt-hours, the maximum power to be supplied being $10 \times 30 = 300$ watts. We must examine successively the two conditions to be fulfilled to satisfy the requirements of duration and maximum rate of working. Let us adopt, for instance, an average type of accumulator cell having a useful E.M.F. of 2 volts, storing 10 ampere hours per kilo of plates, capable of supplying from 1.5 to 2 amperes per kilo, and costing 3 francs per kilo. This accumulator can give 20 watt hours per kilo of plates, and can work at the rate of 3 watts per kilo. To supply the 1,200 watt hours requisite for the period of lighting 60 kilos of plates would suffice, but 100 kilos are necessary to keep 10 lamps working at once without running too close to the maximum rate of

working. The installation will therefore require 100 kilos of plates, costing 300 francs. The selection of the type to be adopted will be suggested by the character of the installation itself. In the particular case before us, 16 or 17 cells must be arranged in series, in order to secure the 30 volts necessary for working each lamp. If the plates in each cell weigh 6 kilo, the capacity will be 60 ampere-hours, which is amply sufficient, since 40 ampere hours only are required. And the maximum rate of supply obtainable is 12 amperes, which is in excess of the quantity required for the ten lamps working at once. If it be desired to charge the accumulators once only in n days, each cell must weigh n times as much as above. In the accumulator we have taken as a type the expenditure for the means of obtaining each useful watt is about 1 franc, and the expenditure for the supply of each watt-hour is about 15 centimes. Thus, for each horse-power hour (736 watt hours) we require to expend in accumulators $736 \times 0.15 = 110$ francs. But the cost for each electrical horse power available is $1 \times 736 = 736$ francs. *Hospitaliers For an hour Protique.*

Gas or Ghastliness. Our contemporary *Money* makes a merry spluttering over the proposed lighting in the City. Surely the acme of conceited infallibility is reached by the writer of the following elegantly critical lines: "If the British public, and the metropolitan British public in particular, do not keep their eyes very wide open they will shortly be enabled by some of the Yankee or other electric light vending fraternity. Foreigners, as a rule, do not come over here for our benefit, and for the last six or seven years first one set of adventurers and then another have been trying all they knew to wheedle, coax, or frighten the holders of gas shares into parting with their property at any price they could get, and inducing them to invest, or rather sink, the proceeds in one form or other of that sickly, spluttering, flickering, deceiving, costly, dangerous, and uncertain thing called the electric light, but which for purposes of practical utility remains almost what it was when first introduced, namely, a scientific toy wherewith to terrify nervous shareholders. And yet, though little or nothing has been done to surmount the great, if not insuperable, difficulties we pointed out several years ago—an exposition which restored the depressed gas shares, then fallen to the alarming figure of about 140, to nearly 200 'we hear,' and 'it is rumoured,' and 'one says' that the old familiar bogey is about to be trotted out again, as though it had not been thoroughly exposed and discredited, both theoretically and practically, over and over again. This time it is said to be Brush-light (not rushlight), respecting which negotiations have long been pending, and upon which the City Fathers are to be persuaded to risk a very large sum of money—far more than the cost of good gaslight—and also to risk something more important still, viz., the safety of the metropolis during the recurrence of those fitful, alarming, and entirely unforetold visitations of sudden darkness that have repeatedly occurred in the House of Parliament and other places where the electric lighters have unfortunately for a time been allowed to have the control of the illuminating arrangements. Crowded as we know that some quarters of London are with hundreds or thousands of native and foreign thieves, rongs, dynamiters, murderers, socialists, anarchists, and the predatory classes of all kinds, the very thought of London being handed over to their tender mercies for even a single night of utter darkness is enough to fill the mind with horror."

SOME POINTS IN THE MECHANICAL CONSTRUCTION OF DYNAMOS.

A great deal has been said and written about those improvements in dynamo design, which might properly be described as electrical, including of course the more efficient arrangement and configuration of the magnetic circuit, prevention of injurious heating, avoidance, or at least reduction, of self induction, suppression of sparking, and many similar points, but speakers and writers on the subject generally dismiss the question of purely mechanical construction with a few sentences to the effect that the machine should be throughout well and substantially constructed. Such a recommendation might almost seem superfluous, if addressed to the designers of dynamos who, by previous experience, including occasional failures of their machines from purely mechanical defects, may be trusted to have now acquired sufficient practical knowledge of the subject, but if addressed to the user of dynamos, who is not also a designer, the recommendation is too vague to be of any practical value. The contractor who buys a dynamo to put up in one of his installations even if he knows nothing of dynamo designing—can generally find out in a trial lasting only a few hours whether the machine he has chosen will be satisfactory from a purely electrical point of view. Sparking at the commutator can immediately be detected, the amount of self induction in the armature coils can easily be found by comparing the electromotive force on open circuit and when supplying full current, provided the exciting power be kept the same in both cases. The limits within which the machine is self regulating either for pressure or current are also easily ascertainable, and a six hours' run at full load will, in most cases, suffice to determine the question of heating. All this is very simple, but when we come to an examination of the mechanical points of the machine, merits or demerits are not so easily discovered. It is true that some very palpable defects, such as inefficient lubrication, insufficient bearing surfaces, want of balance in the armature, or insufficiency of running clearance, can soon be discovered. These are, however, not the only mechanical defects possible, and others of equal importance may only come to light a long time after the machine has to all appearances been successfully started. The electrical features of dynamos receive now so much attention from the makers that electrical failures have become very rare. In the early days of dynamo construction, when the armature was held together by wood, tape, and a little glue, electrical failures generally resulted from mechanical failures, but occurred sometimes also independently. The machines were badly constructed throughout, and it was often difficult to ascribe a breakdown to any particular feature of the design where every feature was bad. Now, however, the majority of failures originate from some purely mechanical defect, and generally from a defect which is not easily detected either by mere inspection or during a trial run.

It must not be forgotten that electric perfection and mechanical strength are in a certain degree antagonistic. Take, for example, the case of the armature winding. To obtain the greatest possible section of conductor, and therefore the lowest possible resistance, the whole of the available space on the surface of the armature should be utilised for the winding, but if we do this no room is left for supports or attachments by which the coils can be securely held and pushed through the field. Thus to make the armature mechanically strong we must sacrifice a part of the available space for the insertion of fastenings, and correspondingly reduce the conductivity of the armature circuit. Or, to cite another instance, to reduce self-induction and sparking it is desirable to employ a commutator with as many sections as there are coils of wire on the armature; but this is only possible in large low tension machines. In smaller machines, and especially if wound for high tension, the number of commutator plates would become so great, and each so thin, that it would be impossible to make a strong and satisfactory job of the commutator. The matter has to be compromised by adopting a thickness of plates just sufficient for mechanical strength, and employing as many of these as can be got in with a given diameter of commutator.

There is, of course, a limit to the diameter, partly on account of expense and partly on account of surface speed, which is one of the factors determining the wear of the commutator and brushes. From a purely electrical point of view it is highly important to subdivide the armature core very thoroughly. In cylinder and drum machines this can be done without difficulty; but in disc machines excessive subdivision means mechanical weakness, and here again it becomes necessary to compromise.

To the user of dynamos mechanical strength is probably of more importance than an exceptionally high efficiency. Since the average machines now in the market return from 80 to 90 per cent. of the power supplied to them, the possible margin of improvement in this respect is exceedingly narrow. A gain of, say, 5 per cent. in efficiency, although worth having, can be too dearly bought if it be accompanied by a reduction in mechanical strength. One breakdown may entail more expense and damage to the reputation of a contractor than could be compensated by the small possible saving in the annual coal bill, and we think users will rather put up with a machine of average efficiency than run the risk of failure with a machine having an abnormally high efficiency. For this reason it is probable that the present limit of efficiency, varying between 80 and 90 per cent., which experience has shown to be compatible with mechanical strength, will not be exceeded. There are, however, points in the mechanical construction of dynamos which do not in any way influence their electrical qualities, and it is to these that we would mainly call attention.

A dynamo is an exceedingly simple machine; a bed-plate, two bearings, a system of fixed magnets, and the revolving armature are all the principle parts. The armature with its commutator spindle and bearings is, indeed, the only part requiring special attention in the matter of mechanical strength, the other parts being naturally of such dimensions as enables them to easily stand the strains to which they are subjected. Now, the problem which the designer has to solve is how to get the power from the pulley (or from the crank-shaft of the steam engine if the machine be direct driven) into the armature conductors which do the work. This is usually done by making the armature core itself assist in the conveyance of power, although there are machines in the market where the wires are held by special fastenings, and the core is not subjected to mechanical strains. Either plan may be good or bad, according as it is carried out. In some machines the wire is simply wound tight over the core and held on by binding hoops. This is hardly satisfactory, as the wires must virtually be carried through the fold by their friction of rest against the surface of the core. Sometimes the fastening is made more secure by little fibre pegs fitted into notches in the discs of which the core is composed, or projecting teeth are left in some of the discs against which the winding rests. Where a Pacinotti core is employed, and the winding placed within the grooves, the arrangement is mechanically perfect. The attachment of the core to the spindle is generally by hubs keyed on; but very often the length and depth of keys is utterly insufficient. We had lately occasion to examine a 20 unit dynamo having a drum armature in which only the end plates of the core were keyed to the spindle. These plates were each $\frac{1}{2}$ in. thick, and the whole bearing surface of the keys was therefore under one square inch. The machine worked apparently well; but every practical mechanic knows that in such a case a breakdown is inevitable, and is only a question of time. By degrees the metal in the key-way, or the metal of the key, but generally in both places, is squeezed away and the fastening becomes loose. To provide against such a failure the best makers of cylinder or disc machines now employ hubs extending almost throughout the whole length of the core, and fixed with long driven keys and not with a feather as formerly. In disc machines the length of the hub considerably exceeds the width of the core. Another important point in mounting the armature is the prevention of its shifting along the spindle. In disc machines this is, indeed, of vital importance, as otherwise there is danger of the armature wires rubbing against the pole pieces, and anyone who has seen the shower of sparks flying round the disc when it touches the pole pieces is not likely to forget the destructive effect of such a failure.

in cylinder or drum machines the shifting of the belt along the spindle may cause a breakdown, and to prevent it is wise to let one hub bear against a fixed collar on the spindle, and to drive the keys from the other side so that the armature cannot come away from the collar by loosening the keys. The practice of using the armature as a collar or abutment for the hubs is strongly condemned, for the commutator can by reason of its construction never be fixed on the spindle with such certainty as to prevent the pounding effect of a heavy armature, should it occur from a defect in the belt or other cause, and in such case the armature and commutator would shift and cause end friction against the bearing. End friction and finally binding may also be caused by a collar on the shaft, if this be not well secured by a lock set screw, and especially if the thread be cut in a direction that a little incipient friction will turn the collar. Wherever possible the thread of such collars should therefore be cut right or left, according to the direction of rotation. It is, however, best not to use collars at all, but to make the spindle stout enough to allow of turning a shoulder on it on either side, the distance between the shoulders should be very small, less than that between the bearings, to avoid end friction and binding if the spindle expands from heat. A common cause may occur from neglecting any of these, but the most common source of failure is insufficient stiffness of spindle. The usual formulae in books are quite misleading if applied to the case of spindles. The reason is obvious. In most mechanical constructions (traction engines, steam diggers, and a few such special machines excepted) we have a fixed limit to the strain in the different parts, and can design their dimensions accordingly. In a dynamo it would not be safe to only provide for the strain which correspond to full output at the normal speed. Users are very apt to overstrain their machines, and dynamos are apt to occasionally short circuit themselves. We question very much whether there is a trained electrician who has not, when testing a dynamo at some time or other made a mistake in his connection, and momentarily short circuited the machine, and a thing cannot even be avoided in the test-room is it to be avoided when the machine is in the hands of a man without any special training. It will happen, and it is the business of the designer to render them innocuous as far as possible. We do not advocate to build machines which can run short circuited for any length of time, but we cannot make a machine mechanically perfect if it will not stand momentarily short circuited. Now, a dynamo having an output 85 per cent. efficiency will absorb on short circuit from five to seven times the normal power, and all the transmitting parts must therefore be able to sustain five to seven times the normal working strain. In calculating the size of the spindle for the normal strain with, say, a factor of safety of six, it is necessary to calculate it for the abnormal strain which may be upon it when short circuited, but in this case we cannot allow so high a factor of safety. As the spindle will only under exceptional circumstances, and for short time, be called upon to sustain the abnormal strain, a factor of from two to three will suffice. To illustrate an example we shall determine the size of spindle for a 20 unit machine running at 500 revolutions per minute. The pulley would be about 18 in. diameter by 4 in. and the transmitted pull of the belt would be 1,380 lb. The strain in the tight side of the belt would be 13,800 lb., so that the total force tending to bend the spindle would be 13,800 lb. The distance from the bearing to the centre of pulley might be taken as 12 in., giving a bending moment of 165,600 inch-pounds. The twisting moment is $460 \times 9 = 4,140$ inch-pounds. Now, according to the well known formula, the moment of resistance against the combined action of these forces is

$$M_r = \frac{1}{k} \left(3M_b + \frac{5}{8} \sqrt{M_b^2 + M_t^2} \right)$$

where M_b is the bending and M_t the twisting moment, k is the strain in lbs. per square inch on the outside fibres

of the material. If the shaft be of steel its breaking strength might be taken as 28 tons to the square inch, and on this supposition k becomes 10,000 lb. If the factor of safety is 6 for normal work, and 3,600 if the factor of safety for the short circuit strain be taken as 2½. The moment of resistance is determined by the diameter d of the shaft, according to the well known formula

$$M_r = .0982 d^3.$$

We can now calculate the diameter of the spindle by using these expressions. For the normal load the diameter comes out as 2¼ in., and for the excessive load due to a short circuit the result is 3¼ in. If the same power were to be absorbed by any other machine, say, for instance, by a centrifugal pump, a spindle 2¼ in. in diameter, would be perfectly safe; but in a dynamo it would be insufficient. If the machine be accidentally short circuited this spindle would be almost certain to break under the sudden strain. We are thus forced to make it about 3¼ in. in the bearing.

A spindle might break not only because too thin, but also on account of its shape. A few weeks ago we had occasion to inspect a dynamo, the spindle of which had broken between the bearing and the armature in a place where failure would be least expected. The grain of the steel was perfectly sound and the area of fracture actually larger than in the centre of the bearing where the strain is naturally much larger. Insufficiency of dimension could therefore not have caused the fracture. It was evidently due to the fact that some sharp angular grooves had been turned in the spindle to throw the oil off, and although the diameter of the spindle at the bottom of the grooves was still larger than in the bearing, the continuity of the fibre of the material had evidently been spoiled by turning these grooves, and thus the fracture was started. To avoid such failures all shoulders and collars should be turned with a fairly large radius, and discs to throw off the oil should be entirely separate from the spindle.

There are many other points in connection with the mechanical construction of dynamos which merit attention, but as to deal with these would exceed the limit of space now at our disposal we must leave the further consideration of this subject to a future occasion.

PRACTICAL ELECTRICAL UNITS.

BY W. B. ESSON.

(Continued from page 57.)

The engine which drives a dynamo is described as of so many *horse power*, and the latter expression introduces us to the system of units employed by the mechanical engineer in estimating the quantity of work performed, and the rate of its performance. His method of measurement must be fully comprehended, for it is often necessary to measure the mechanical work expended in driving machines as well as the electrical work obtained from them. Between the mechanical units which follow and the electrical units just described there exist perfectly definite relations which must be understood and formulated before we can deal with the problems which will hereafter present themselves for solution. In the equations following the student will doubtless discern a resemblance in form to those preceding.

8. *Force.* Force may be defined as any cause which changes or tends to change the motion of a body by altering either the quantity or the direction of that motion. The engineer measures a force by the weight it will support, or by the pressure it will exert, and has chosen as his unit the force which will support a weight or exert a pressure of one pound avoirdupois, this being termed for brevity a *force of one pound*.

9. *Space, Velocity.* The foot is generally adopted as the unit of space, and we may select as unit velocity one foot per second. A velocity of one foot per second expresses a rate of progression such that, were the motion to continue uniform for one second, the space passed over would be one foot. Calling S the feet passed over in t seconds and v the velocity in feet per second, the relation between

space and velocity, the motion being uniform, is expressed by

$$v = \frac{S}{t}.$$

10. *Work*.—Work is done when a resistance is overcome through a space. To overcome resistance force must be applied, the magnitude of the applied force being a measure of the resistance encountered. The work done is directly proportional to this force and to the space through which it is applied. It is measured by the product of force and space, the unit being the *foot-pound*, which is the work performed in lifting a weight of one pound through one foot or the work done in exerting through one foot a pressure of one pound. If 200 pounds are lifted 10 feet the work done is $200 \times 10 = 2,000$ foot-pounds. The same amount of work is performed if the weight is 10lb. and the space 200ft., since its quantity depending only on the product is independent of the value of the individual factors which make it up. If we call P the force exerted in pounds and F the work done in foot pounds, then assuming that the force remains uniform

$$F = S \cdot P$$

11. *Rate of performing work. Power*.—As in the case of electricity we require more frequently to know the rate at which electrical work is being done at the moment of observation than the quantity performed in a certain time, so the engineer more often desires to know the rate at which mechanical work is being done than to know the number of foot-pounds performed in a day or an hour. The unit rate of performing work must necessarily embrace the idea of time. Though $S \cdot P$ gives the amount of work performed by a pressure, P , exerted through a space, S , obviously the product affords no clue to the time which the work has taken to perform, and the quantity it represents may have been produced by a man turning a handle for 10 hours, or a steam engine working for 10 seconds. Velocity in feet per second being represented by v , to obtain the rate of doing work in foot-pounds per second we have simply to multiply P by v instead of by S , the rate of performance or power at any moment being the product of force and velocity.

A rate of one foot-pound per second would be a unit too small for practical use, and accordingly a larger unit, termed the *horse-power*, of 33,000 foot-pounds per minute or 550 foot-pounds per second, has been adopted. The difference between "foot-pounds" and "foot-pounds per second" should be clearly perceived, the former being a quantity, the latter simply a rate. Everyone recognises the difference between a velocity of 60 miles per hour and a distance of 60 miles, but the difference between power and work is not so readily comprehended. By a velocity of 60 miles per hour we convey the fact that were a train to move at uniform speed for one hour it would cover a distance of 60 miles, so by the term horse-power we convey the idea that were work delivered to a machine at uniform rate for one second the foot-pounds in that time would amount to 550. By a velocity of 60 miles per hour is conveyed no inference that the train will run for one hour, nor is it by the term horse-power assumed that the particular rate of one horse-power will be maintained for a second, for both velocity in the first case and power in the second may be continually varying. But we do imply by these terms that at the moment of observation a certain ratio exists between space and time in the one case and work and time in the other. In the case of a varying power, if we measure the work done in the fraction of a second, in a period of time so small that during its continuance the rate of work may be assumed uniform, and divide the work done by the time, an approximation to the rate of doing work is obtained which gets closer to the true answer as the time becomes smaller and exact when it is infinitely small. Though in a second 550 foot-pounds of work are done, it does not follow that for the whole time the work has been performed at the rate of a horse-power. In the second the power may have varied anyhow, the work at the end of the time still being 550 foot-pounds. But the power at any moment is truly expressed by the ratio of work to time as above defined. Calling $H.P.$ the horse power, the relation be-

tween power, velocity, and force are given by the expression

$$H.P. = \frac{v \cdot P}{550}.$$

If for velocity in feet per second v , we substitute velocity in feet per minute v_1 , the expression becomes

$$H.P. = \frac{v_1 \cdot P}{33,000}.$$

(To be continued.)

ON THE INFLUENCE OF TEMPERATURE UPON THE MAGNETISM OF IRON.*

BY M. P. LEDEBÖR.

It has long been known that a magnetised bar loses its magnetic properties when heated to redness, but the temperature at which iron ceases to be a magnetic body has not hitherto been determined by direct experiment.

Many physicists have occupied themselves with these researches. Prof. Rowland (1873), who was one of the first, determined the magnetic permeability of iron in absolute measurement; this writer, experimenting up to the temperature of 230deg. (centigrade), did not observe any difference in the properties of iron. M. Polon (1882) and Mr. McRae (1885), with temperatures reaching 280 and 300 degrees, observed only slight variations. M. Berson (1886) operated at temperatures reaching about 340 degrees. This writer showed that nickel suddenly loses its magnetic properties towards 300 degrees, in regard to iron (and cobalt) no diminution is observable at this temperature. The fact is that iron remains magnetic up to 650 degrees, and it is only at higher temperatures that a rapid variation in the magnetism is observable.

Method Employed. We have measured the relative value of the magnetic permeability of iron by measuring the coefficient of self induction of a coil containing the bar of iron operated upon. In order to eliminate the induction due to the coil itself, a second similar coil was inserted in the opposite side of a Wheatstone's bridge; it is found that, in the absence of the bar of iron, the bridge is in equilibrium both with a continuous current, and when the extra current is brought into play. On a former occasion we showed that the quantity of electricity in the extra current is proportionate to the magnetic moment of the bar, or to the magnetic permeability.

The magnetic permeability cannot be determined in absolute measurement by experiments on a relatively short bar; for we do not know how to calculate the effect due to the extremities of the bar. Neither have we determined the residual magnetism; since this factor also is dependent upon the form of the bar. It is known that the residual magnetism is inversely as the demagnetising forces in action.

Apparatus for heating.—The bar being placed within the magnetising coil, it is necessary to heat it without raising the temperature of the latter, not only in order that the insulation may not be destroyed, but also in order that the resistance may not be varied. The production of heat is obtained by means of a spiral of platinum traversed by a voltaic current; this spiral is wound double (on a sheet of mica surrounding the iron) in order that it may not react upon the bar.†

In order to measure the temperature, a thermo electric couple of M. Le Châtelier (pure platinum and platinum rhodium alloy) is introduced between the spiral and the iron; this couple also being insulated by means of mica. The graduation of this thermometer was taken as having been carried out at the temperatures of 100deg., of 340deg. (NH_4Cl), of 665deg. (Sn), and of 1,015deg. (K_2SO_4) according to the directions of M. Le Châtelier.‡

* Note read before the *Académie des Sciences* by M. Lippmann Jan. 9th 1888.

† (This is somewhat obscure, what is probably meant is that there are two spirals traversed by the same current in opposite directions. *Et. E. E.*)

‡ Le Châtelier, *Journal de Physique*, 1887; Vol. IV. p. 11.

results obtained.—The annexed diagram shows the results obtained with a bar of soft iron from Berri, subjected to magnetising forces of 35, 100 and 200 C.G.S. units. It will be seen that at temperatures below 660 degrees the iron

possesses sensibly the same magnetic properties as when cold, but that beyond this temperature the fall is very rapid, and at 750 degrees, these magnetic properties scarcely exist, and at 770 degrees they have completely disappeared. A sudden variation occurs, therefore, within an interval of temperature of 80 or 100 degrees. As soon as the iron is cooled to cool, the magnetic properties reappear as they formerly existed.

In his recent researches on the specific heat of iron at a high temperature, M. Pouchon* showed that iron undergoes a change of condition between 660 and 720 degrees; it will be seen from the preceding experiments that iron loses its magnetic properties between 660 and 770 degrees. The agreement between these figures obtained by altogether different methods, in which the temperatures were measured by different methods, is certainly a remarkable fact.

THE LAHMEYER DYNAMO.

There has recently been brought out in Germany a dynamo machine which is said to give very good results,

FIG. 1.

in which the construction adopted is worthy of notice. The principal idea embodied in the construction is the re-

duction, as much as possible, of the magnetic resistance; and in order to accomplish this the first step taken was to adopt a construction which would permit of as little scattering of the magnetic lines of force as possible, and at the

FIG. 2.

same time avoid joints in the magnetic circuit which offer more or less resistance to the magnetic flow. The machine constructed with this design in view is shown in perspective in Fig. 1, and Figs. 2 and 3 show respectively a transverse section and end view of the machine. The pole pieces,

FIG. 3.

which are quite short, are surrounded by coils which generate lines of force that branch out and pass over by the paths BB' in the direction of the arrows shown. In order to avoid as much as possible the branching of the lines of force from pole to pole outside the armature, the

FIG. 4.

distance, ab , between the poles is made as large as possible. The whole machine, together with the base, is cast in one, so that it presents a most compact appearance. The armature of the dynamo is of the Siemens drum type, and is built up of soft iron discs insulated by thin paper washers.

FIG. 5.

At suitable intervals the plates are separated, and through these the air passes up, being admitted through the vent-holes L, at the end of the armature, shown in Figs 4 and 5. In this way the armature is prevented from over-heat.

* *Comptes rendus*, Vol. CIV, p. 135, 1887.

In a glass cell containing sulphuric acid, C. P. Sp. Gr. 1.81, temp 75° F., two electrodes were immersed, one of platinum, the other of lump graphite; only a slight E.M.F. was indicated, 0.007 volt, due to the combination, the graphite acting as a positive element. On the addition of a small quantity of chlorate potassium to the acid, the E.M.F. immediately rose to 0.08 volt, the graphite being disintegrated after a time. This cell polarised rapidly, which was partially prevented by mechanical means. The reaction of chlorate potassium with sulphuric acid may be represented by the following equation: 3KClO_3 (chlorate of potassium) + $2\text{H}_2\text{SO}_4$ (sulphuric acid) = 2ClO_2 (peroxide of chlorine) + K_2ClO_4 (perchlorate potassium) + 2KHSO_4 (acid sulphate of potassium) + H_2O (water).

A method of exclusion was adopted to ascertain the oxidant of this electrolyte: chlorine peroxide (ClO_2) appeared to be the only active agent. It is decomposed by the carbon, chlorine being evolved with some oxygen. It was assumed that in this cell graphitic acid ($\text{C}_2\text{H}_2\text{O}_3$) was formed* as the result of the chemical actions. There is probably much waste of energy through local action, as the chemical reactions go on when the circuit is open, but to a less extent. In another experiment an electrolyte was formed of sulphuric acid and chlorine peroxide, the gas being formed in a retort by the action of sulphuric acid on chlorate potassium, and conducted over into the acid in which it was dissolved. This cell, with a positive element of graphite, opposed to platinum, gave an E.M.F. of 0.7 volt†.

A similar combination was used with a solution of chlorine peroxide in water as the electrolyte. The E.M.F. assigned to these cells is only approximate, as it was found dependent on the quantity of chlorine peroxide in solution, which was constantly changing. The resistance also varied with the different degrees of concentration of the exciting fluid.

Different forms of amorphous carbon were substituted in place of graphite in the first form of cell. Gas carbon gave an E.M.F. 0.007 volt when opposed to platinum in sulphuric acid; on the addition of chlorate potassium the E.M.F. rose to 0.5 volt.

Carbon, produced by the action of sulphuric acid on cane sugar, in this experiment gave an E.M.F. of 0.3 volt.

The carbon of animal charcoal, wood charcoal, coke, and anthracite, gave an E.M.F. variable with each form, ranging from 0.3 volt to 1.25 volt. The measurements of E.M.F. of the various combinations were made with the electrode immersed in separate parts of the same solution, that the concentration of the liquid and quantity of gas in solution might be as nearly equal in each cell as possible. It was found when the carbon in comminuted form was contained in a porous cup that the combination gave an E.M.F. of 1.24 volt, apparently due to the presence of the oxygen of the air.

It is impossible at the present stage of the investigation to assign any definite value of the E.M.F. to these forms of amorphous carbon. In some cases they appear to have an E.M.F. higher than that of graphite.

The energy of the combination of carbon and oxygen when completely oxidised to (CO_2) carbonic acid gas is stated to be 9,621 foot pounds per grain equivalent, which is 2.6524 equivalents. In these carbon elements the E.M.F. is not so high, as there must be deducted the counter E.M.F. of polarisation, and the energy due to the force of setting chlorine free.

A resort to chemical analysis, of the products formed by the reaction in the cell, indicates the following conclusions:—

1st. Carbon produced by the action of sulphuric acid on cane sugar proved to be partially oxidised, or impure carbon.

Analysis gave the following values:—

C	62.20 per cent.
H	1.61 per cent.
O	36.19 per cent.

* See *Q. Journal Chem. Soc.*, Vol. XII, October, 1883.

† Great care must be taken in the preparation of this gas, as it explodes at a temperature of about 140° F. It can be preserved in the dark, and is decomposed by sunlight into its component parts.

‡ See Sprague's *Electricity*, p. 519.

Analysis proves that ($\text{H}_2\text{SO}_4 + \text{KClO}_3$) sulphuric acid + chlorate of potassium oxidises carbonaceous bodies, like the above product of (H_2SO_4) sulphuric acid on cane sugar, to CO_2 , and, further, that such bodies first are changed to compounds soluble in the acid (caramel-like substances), which are rapidly oxidised to CO_2 .

2nd. Battery carbon of the composition

C	96.20 per cent.
H_2O	70 per cent.
Iron, SO_2	2.30 per cent.

The fact was shown that this form of carbon can be oxidised to CO_2 .

3rd. Wood charcoal, of the following composition after ignition:—

C	94 per cent.
H_2O	5.5 per cent.
Silicious res.	5 per cent.

This, after repeated re-ignition, was oxidised by the electrolyte to CO_2 , no intermediate compounds being formed, and further, in case of pure amorphous carbon the oxidation is complete; that is, that all the carbon is oxidised to CO_2 .

These analyses were made with the solution at a temperature of 122° F. to hasten the action, the carbon being in contact with the platinum. In these elements the oxidising material is too expensive for practical use.

Undoubtedly the direction of experiments in the future will be to find some cheap substance which will absorb oxygen from the air and give it up to the carbon; in fact, acting as a carrier of oxygen, so oxidising it without heat; and this is not impossible, as we already know of substances which do this, though giving a low E.M.F.: thus, for instance, the ferric salts are reduced to ferrous by agitating their solutions with carbon, being regenerated by absorbing oxygen from the air.

By pursuing this line of investigation we can be sure we are not ignorantly striving against any law of nature when attempting to convert the whole potential energy of carbon into electrical energy.—*Electrical World*.

THE SCHOOL OF ELECTRICAL ENGINEERING.

Many of our readers are fully acquainted with "The School" in Prince's street, Hanover square. A goodly number of those engaged in electrical work have passed a period of preparation therein. Instituted in years gone by for the purpose of preparing students in the requirements of the telegraph service, it has had to change its curriculum with the altered condition of things due to the development of electric lighting. An electrical engineer is not now one familiar with the working of the Morse instrument, or of Thomson's recorder, with the testing for faults in cables, or the general manipulation of apparatus actuated by comparatively minute currents. "Other times other manners" applies to electricity as elsewhere, and unless "The School" progressed with the times it would drop out of the race and become a matter of history. In fact, in order to fill the position without adverse criticism, "The School" should be a little ahead of the time: its management and its lecturers should always be on the look out for what is in the air, and may become an actuality in the near future. That a successful effort is made to keep abreast of the times is seen from the recent addition to the "practical part" of this school. Last year a new machine room and workshop, illustrated on p. 84, were organised, and are now in full work. It will be seen that the engine room contains both gas and steam engines. This is as it should be, for every electrical engineer should be fully acquainted with the vagaries of both kinds of engines, if their makers will concede that they have any. The teaching cannot well be too practical. The time spent in such an establishment is insufficient to permit of general education, and everything, therefore, being of a special character, should be used as a means to an end. The end aimed at is to fit the student for a position in some special branch of electrical engineering, and those best able to judge how far the curriculum is calculated to do this are those who have passed through the school and are now engaged in actual work.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY, with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newspaper in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months.	6 months.	12 months.
United Kingdoms...	3s. 3d.	6s. 6d.	13s. 0d.
Within the Postal Union	4s. 4d.	8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

BRUSSELS EXHIBITION.

In May next this exhibition will be opened, and no doubt many English travellers will make the exhibition an excuse to visit Belgium. It has occurred to us that perhaps, either going to or from Brussels, most travellers to Belgium will visit the historic towns of Antwerp, Ghent, and Bruges. We have therefore arranged with the proprietors of the engravings to give as supplements several steel engravings illustrating Belgian scenes. These will be issued at intervals before and during the exhibition. The first of the series, issued with our current number, illustrates one of the most picturesque scenes in Ghent—the old houses at the water-side.

IN THE WAY OF BUSINESS.

There is a more or less roseate hue surrounding almost all branches of business just now, which is gratifying if for no other reason than "hope springs eternal in the human breast," and the hope is that business will continue. In our opinion there is much reason for hope so far as electrical work is concerned. Business is progressing on legitimate lines, and the speculation or the speculation which gives the deathblow to honest work, only occasionally raises its hydra head to lose it—in other words the public will not speculate. When the world was first told that gas as an illuminant was a thing of the past, that electricity would certainly supersede it in weeks if not in days, the world believed and wondered; and has gone on wondering ever since why it was so easily duped. In reality the Electric Light was ushered in as a luxury. Its development and extension was as a luxury, except perhaps in such cases when the pure light was required to aid the matching and judging of colours. In the latter case the question of expense was hardly one for consideration, and the use of the electric light in such places must not be considered when reviewing its general progress. The apparatus for the generation, distribution, and measurement of electricity in 1882, when the Electric Lighting Act was passed, was crude in comparison to what it is now, and all sensible persons must acknowledge that at that time any work carried out on a large scale for general lighting would probably have been very costly, even if it had not proved a total failure. Since then successful experiments have been made. These experiments have opened our eyes to weak spots in the original systems, which weaknesses have been to a great extent remedied, and it is not too much to say that there are half-a-score of firms among us who might be trusted to successfully light a moderately-sized town with a mixture of arc and incandescent lighting.

A good deal has been said lately about central station lighting in England, but as a matter of fact we as yet have not got a single central lighting station worthy the name. The largest, that at Paddington, is a private concern to light a railway terminus. Brighton, Eastbourne, Taunton, Sheffield, &c., are none of them larger than many a private installation, nor are the difficulties their managers have to encounter equal to those which would have to be met in a case of general distribution over a whole town. The Grosvenor Gallery is often referred to as pointing out what can be done, and with this we entirely agree; it shows what can be done, but that is quite a different thing from doing it. The majority of these experiments have been successful, not because of a well thought-out scheme *ad initio*, but because of the brains superintending the operations constantly suggesting alterations and modifications to meet emergencies. Perhaps the best-considered scheme from the commencement is that at Kensington Court, but in this instance the case presented exceptional

features, and difficulties to be met with elsewhere had no existence.

We frequently meet with the statement that in England we lag behind our friends across the Atlantic and on the Continent. This statement is false and generally malicious. Although England can hardly claim the original ideas which led to the recent development of dynamos, we can confidently claim that given the ideas it is our practice that has been followed and copied on all sides. It is to England that "output" for weight, as a constant aim of designers of dynamos, is initially due. So far as the principles upon which such machines are now constructed, the world is largely indebted to Hopkinson and Kapp. But the object is not to determine the part England has taken, but merely to indicate that we dispute the attempts to take away the honour justly her due in this direction.

When we come to the adoption of arc lights for street lighting, America is far and away ahead of us, but the conditions are entirely different, and it would be surprising if the light had not been adopted in America in its earliest stages. It is singular, however, to notice that while the Americans are almost universally adopting the arc lights, the spread of incandescent lighting, and in fact the lighting of interiors generally, by no means keeps pace with the street lighting. In America the natural order of things was for street lighting to come first; in England its place was last. Private mansions, factories, railway stations, ships, and mines present a field to be worked before streets and houses, and in these directions success has been abundant. There is still an immense amount of work to be done, but every factory lighted brings us nearer the time when in such places the electric light will be the rule and not the exception. Do our business men concern themselves with the future, then look out for every hint of a new mill to be built. It is easier and cheaper to install the electric light in a new building before the gas pipes are laid than after they are laid. It is easier to arrange for twenty or forty extra horse-power when the mill boilers are being designed than after they are in position.

The modification of the Electric Lighting Act of 1882 will not mean the opening out a field of business for every firm. The large works connected with central stations mean the use of large capital, the straining of resources to the utmost, the promoting of local companies, and the finding of the "needful" till the local concerns are well afloat—conditions altogether outside the capabilities of the smaller firms. A leaf in electric lighting development may be taken from the experience, say, of the Silvertown Company or of Messrs. Siemens and others in cable work. If these companies had waited till the world came to them for cables, they would have waited a long time. It is useless, however, to enter into this business till the road is clear and unimpeded by legal obligations, which hang like millstones round the necks of those whose cry is "Forward."

Just as the conditions which hold in America relative to lighting differ from those which hold here, so do the conditions which hold with electric traction. In America the signs of the times are that electric traction will on tram-lines entirely supersede horse and steam traction, and the change is being carried out at a rapid rate.

Last week we made a suggestion to the Society; there is another we would make if it were needed. Papers have lately been read on fuses, and on measuring instruments. These might well be followed—and we believe that arrangements have been made that they should be followed—by papers on transformers and on electric traction. The capability of transformers needs discussion. Electrical engineers are at sixes and sevens on the subject; but the most important bearing is the effect of such papers on the purchasing public. The Institution of Civil Engineers has recently devoted several evenings to the discussion of electric traction, but the result of the deliberations has as yet played no part in influencing public opinion towards or against such method. "The same thing over again." Yes, decidedly. The inertia to be encountered is immense, and the impress of authority must be given to every step before the workers can hope to progress far in its application.

CABLE COMPANIES' MEETINGS.

Our reports show that within the past few days two important cable companies have held their meetings, and in both cases the shareholders were congratulated upon the results of the past half-year. The Direct United States Company, however, is not in the position of the Eastern Company, the latter declaring a good dividend, the former hoping for one. It is the duty of a chairman to keep the shareholders in a good humour, hence Sir J. Pender pointed out how nearly the Eastern Company had recovered from the blows of the Berlin Conference. The recuperative power has been shown to be great. The shareholders will have to look forward as well as backward. The action at Berlin will undoubtedly be followed up and intensified at the next Conference, and although the directors are quietly and systematically working to make their positions secure, they will need to take the shareholders more into their confidence, and to enlist the sympathies of a wider and more powerful public, if they are to hold their own. The cable companies have managed to raise up a nest of hornets about their ears at recent conferences. France bears them no good-will, and will probably bear ill-will, because of the success of the Anglo against the French Companies; for outside England there exists clanism or patriotism which sometimes interferes with reasoning, and leads those whose actions should be above suspicion to follow the dictates of financial circles. Germany is blunt and outspoken, knows her own mind, and generally manages to get what she wants. The great danger to the management of cables going eastwards is

in the action of our Australian Colonies and Canada. Will the Pacific scheme go through, or will those over whom Sir J. Pender presides take the bull by the horns and lay these cables themselves? We think they will.

LITERATURE.

Lessons in Elementary Practical Physics, by BALFOUR STEWART, M.A., F.R.S., and W.W. HULLANE GLE, B.Sc. Vol. II., "Electricity and Magnetism." [Macmillan and Co.]

Professor Flemings' lectures at Chelmsford, published in the latter part of 1886, followed by the volume by Prof. Ayrton, and by the work above mentioned, has given, so to speak, a new impetus to electrical literature of the best kind. In so progressive a subject as electricity has of recent years proved to be, the difficulty of text books is to keep pace with the subject. The deficiencies of text-books are, however, recompensed by the technical journalism of the day, and it is necessary for the student not only to master his text books, but also to make himself conversant with the more ephemeral literature, if he would keep himself abreast of modern progress. We do not recognise as text books that large class of books designed only with a view to assist readers in passing examinations. Nor do we recognise as students those readers whose goal is the passing of an examination. The slinger of symbols is a product of the examination mania, but the most credulous only accept the product as classed "Al at Lloyd's." The books named have no direct connection with examinations, although the one at the head of this notice is admirably adapted for the use of masters, who can rid themselves of the trammels of calendar and syllabus. The plan adopted is to subdivide the matter "into a series of lessons, each descriptive of something to be done by a definite method with definite apparatus." We have read very carefully a large number of these lessons: there are in all 83 lessons besides appendices, and in every case have had to pronounce them good. The apparatus required during the lesson is first described, then the use of the apparatus, the phenomena shown by it, and the principles illustrated and deduced therefrom. Old Humphry in his writings dubbed the sample plums or potatoes laid carefully at the top of the basket as "toppers" and not fair representatives of the whole. The critic has power to select unfair samples if he chooses from any author—either super-excellent or inferior. We think an author's matter and method can best be shown by an example, and for this purpose select a portion of a fair average lesson. This lesson, XLIII., is on the Use of Standard Galvanometer in the Determination of E.M.F. The authors give as the special exercise "To find the E.M.F. in volts of a Groves cell." The apparatus required is then stated, followed by the theory of the method which results in obtaining the formula $E \text{ (in volts)} = \frac{10 H I}{\tan a - \tan a_1}$. The method to

be pursued in practice is then described, and an example fully worked out. The result of the example gives $E = 1.76$ per cell, the authors pointing out this is too low because of the presence of local iron. The last paragraph of this lesson relates to *Electro-Chemical Equivalents*, and is as follows:—When an electrolyte is placed in a galvanic circuit the amount of chemical decomposition in unit time for unit strength of current is a fixed quantity. The mass of substance liberated at the electrode is called its electro-chemical equivalent. The equivalents for certain important elements have been determined with great accuracy by Lord Rayleigh and others. Thus the amount of silver deposited from silver nitrate in one second by one ampere of current is .001118 gramme. By the aid of this number the electro-chemical equivalent of any element can be found if we know its chemical equivalent, for if the same current be sent in succession through different electrolytes the amount of the elements deposited at the electrodes would be in the ratio of the chemical equivalents. Thus we have—

Chemical equivalent of silver = 108
" " hydrogen = 1

Hence the electro-chemical equivalent of H is

$$\frac{.001118 \times 1}{108} = .00001035.$$

Again, since the chemical equivalent of copper in the cuprous state is 31.5, the electro-chemical equivalent is

$$\frac{.001118 \times 31.5}{108} = .000326.$$

Let W denote the mass in grammes liberated at one electrode by a current of strength C in t seconds, and let e be the electro-chemical equivalent then we have

$$W = C e t, \text{ or } C = \frac{W}{e t}.$$

This will enable us to measure currents by ascertaining the mass in grammes liberated in a given time.

In the case of water it is customary to determine the total weight of water decomposed. Now an ampere in one second—in other words a coulomb—will liberate .00001035 gramme of hydrogen and eight times the weight of oxygen, or .00008280 gramme. Hence a coulomb will decompose .00009315 gramme of water. If instead of weighing the water we measure the volume of one or both the gases liberated, it will be convenient to know the relation between the volume of these and their weight. Now 1 gramme of hydrogen measures at 0 C. and 760 mm. pressure 11170 cubic centimetres. By aid of this number it will be easy to convert the weights into volumes. The resulting values and others that are also useful are exhibited in the following table:—

TABLE I.—Electro-Chemical Equivalents.

	Grammes per coulomb.	Normal cubic centimetres per coulomb.
Hydrogen00001035	.1156

ELECTRIC TRACTION.

On Tuesday a number of gentlemen were invited to Chiswick to examine a tramcar driven by electricity. However we may desire the period to come when horse traction will be superseded by electric or other traction for tramway work, we cannot forget that a number of successful experiments have been shown in and around London, yet no progress, so far as regards actual work, can be chronicled. Inventors, if the slight modifications to existing systems warrant that title, keep pegging away to achieve success,

FIG. 2.

FIG. 1.

and such persistency is bound, sooner or later, to meet with its reward. It is easy to arrange a perfectly successful experiment on a scale similar to that of Tuesday. The running line was not more than 100 yards or so in length, and of course absolutely free from most of the troubles of an actual working line. The Lineff system shown is a central channel system, in which channel is carried the conductor. The improvement claimed is in the method of making contact. Let us, however, begin with the central channel, which is closed at the top, except for about an inch through which the contact carrier passes. On the side of

the channel is a piece of wood, carrying arms at intervals, upon which the conductor rests, but insulated from the arms. The conductor is copper drawn through an iron pipe. If we may be allowed to criticise the arrangement, we might ask the value of the copper at all. At intervals of five or six feet the iron pipe is tapped, and a contact piece, Fig. 1, screwed tightly down upon the copper. Would it not be cheaper and quite as well to have a solid iron conductor into which or upon which the contact pieces could be screwed or fixed, making good contact? The conductor is some two and half inches from the vertical through the opening of the channel, and so free from likely contact with foreign substances. Of course the channel is so arranged as to be of considerable depth below the conductor, that water getting in would naturally drain off, and mud would be occasionally flushed out. (Fig. 2)

Contact is made from the car by means of a carrier through the slot into the central channel carrying a flexible rod sufficiently long to always rest upon two of the contact pieces. While the car is running all contacts will be kept bright and clean, so that no difficulty need be anticipated at this point. A street channel of the kind described will always be damp, and considerable leakage will occur if the present device is insisted upon. Surely the powers of electrical engineers are equal to so simple a demand as that of a conductor with little chance of leakage. An iron rod embedded in pitch, or some cheap insulator of that type, with only the contact pieces projecting, would give far less leakage than the form adopted. If copper is a *sine qua non*, why not put it into an asbestos sheath? Water will always be formed upon, and be found dropping from the iron pipe. Why cannot some electrical engineer who really understands the first principals of the subject get "financed" by the tramways, or promoters who are eager to spend money upon crude experiments? There really seems to be no valid reason why electrical tramways should not succeed on a large scale. They ought to be cheaper than horseflesh, and those exponents of the system who have had some experience maintain that they are cheaper. The motor used in the experiments we have referred to is a 5 h.p. Immisch motor, running at 1,000 revolutions when the car is going at the rate of 6½ miles per hour. The dynamo supplying the motor is also by Immisch. Some of the details of the car and the brake used are new, but to adequately describe the whole, further illustrations are necessary, and these we hope to give in another issue.

THE HYDRAULIC ARC REGULATOR OF M. BERTHIER.

This lamp, which, we think, should have preceded, in the natural order of inventions, other apparatus better adapted to the general requirements of practice, requires, it will be seen, to be in connection with a supply and discharge pipe for water. In some exceptional cases, however, this might be no objection, and, as the arrangement has the merit of simplicity, we will briefly bring it to the notice of our readers.

Referring to the diagram, the upper carbon is fixed, whilst the lower one is mounted on a piston, Z, which moves within a cylinder, P, the lower portion of which communicates by a pipe with the reservoir, X, supplying water at a certain pressure. In the tube is a tap, R, in connection with the soft iron core, A, of a solenoid, B, through which passes the current supplying the lamp.

At starting, since the core A is not attracted into the interior of the solenoid, its weight opens the tap R, and thus establishes communication between the reservoir X and the cylinder P, causing the ascent of Z, until the carbon attached to it strikes against the upper carbon. If, now, the lighting current be switched on, the water supply is stopped by the closure of R through the attraction of A into the solenoid, and in a few seconds an arc is formed between the carbon points. When the distance between the latter becomes too great, the diminution of the current brings about a flow of water through which the lower carbon is raised until the current regains its normal strength,

and again causes the communication between X and P to become closed at R. The apparatus being once properly

adjusted, a very steady light is said to be by these means obtained.

JUVENILE LECTURES.

The Royal Institution and the Society of Arts deserve the best thanks of the scientific community in that they systematically provide juvenile lectures, which are given by some of the most eminent scientific men living, generally during the Christmas holidays. This year the lectures at the Society of Arts were given by Mr. W. H. Preece, F.R.S., and were on "The Application of Electricity to Lighting and Working." The first of these lectures, which was delivered on January 4th, has just been published in the society's *Journal*, and from it we take the following extracts which may probably be interesting to those who were unable to attend the lectures, and may, perhaps, not be uninteresting to older people who have not had the advantage in their earlier days of attending such lectures. With regard to the cause of illumination, Mr. Preece said: "In all cases of artificial illumination bodies have to be raised to a high state of temperature. I hold in my hand a piece of magnesium wire, it is really flat magnesium tape, but it is called wire. If I heat that you will observe that a very brilliant light is produced, due to the very high temperature at which it burns. Now, if I take a lump of coal and heat it, it requires to be raised to a certain temperature before the oxygen is directed upon it, and subject it to a jet of oxygen, you will see that it burns with very much more intense light than you are accustomed to in the ordinary fire. If I take a piece of iron wire and place it in a jar of oxygen, you see what a very brilliant effect the combination of oxygen and iron produces through the iron being raised to a very high temperature.

"I have now shown you that in order to produce light we must, by some means or other, raise the temperature of a body. But the high temperature that we have to deal with is not that produced by the combination of the oxygen of the air and carbon, and other bodies such as I have shown you, but it is produced by the aid of the electric current. In all these cases the result of the combustion you have seen has been to remove oxygen from the air, but now I want to show you how a body can be raised to a high state of temperature without combustion of any kind. In front of me I have a fine platinum wire. In my hand I hold a wire that is in connection with a battery upstairs, the other wire in connection with the battery is attached to the far end of the fine platinum wire, now, when I make contact with the near end of the platinum wire, you observe that the wire is raised to redness, its temperature is high, and as I reduce the length of the platinum

wire it gets brighter and brighter, the amount of electricity passing through it is greater and greater, and presently the wire is fused. I should have pointed out that as the quantity of heat generated in a wire increases, so does the colour of the light. When heat is applied to a body, that body is first warmed, then it gets gradually hotter and hotter, until it becomes red hot, and the first colour that appears is always red. The temperature is further raised, and the body assumes the colour of orange, then at a little higher temperature it appears yellow, and so the different colours of the rainbow are perceived according to the different temperatures to which the body tested with is raised. And now I want to show you the most intense form in which heat can be produced on this earth. There is no hotter object that we can obtain than that of the electric arc. I will try and produce this arc. You observe that when I bring these two pieces of carbon together a current of electricity passes between them, and the passage of the current of electricity between them creates such an intense temperature that a brilliant white light, as you see, is produced. Incandescent particles of carbon pass between the two points, forming a sort of bridge or arch, which is called the electric arc. But the temperature of this arc is, as I said before, the highest temperature that we can produce; it has been measured, and is found to be 8,500 degs. Fahr. That is a temperature that can hardly be conceived; the melting point of iron is only about 1,200 degs. Fahr., the melting point of platinum, which is one of the most refractory metals we have, is about 3,000 Fahr.; but here in the arc we have the intense temperature that nothing can withstand, equal to 8,500 degs. Fahr. The colour is really due to the combustion that takes place between the materials forming the arc. I have just used two pieces of carbon, but I will now try other materials—copper, iron, and zinc. You will see a difference in the colour of the light, due to the fact that metal is burned in the arc instead of carbon. Every metal has its own distinct and particular colour, and the presence of the different metals can be detected by the character of the small arcs produced.

"I have shown you that we have two modes of producing intense heat, and therefore light, by electricity. I want now to show you how we produce electricity. The first essential for the production of electricity with a hand machine like this is a good dinner. The energy provided by beef or mutton enables the operator to turn the big wheel of the machine, whence motion is transmitted to the apparatus for producing the electricity. This machine when rotated causes a coil of copper wire to be whirled in a magnetic field, and that rotation of the coil in a magnetic field converts the energy derived from the grass and the mutton through the machine into electric currents; those electric currents flow through wires that are under the table, they will appear in the two wires I hold in my hand, and will, I hope, reappear in the little glow lamps I have before me in the shape of heat and then of light when I attach the wires. The light of the glow-lamp is of just the same form of energy as that which passed from the sun to the earth, and, by beginning backwards from the lamps we have light, heat, electric currents, mechanical motion, food or fuel in the shape of mutton, grass on the South Downs, to the sun. Whichever way it is taken you will find there is direct action between the sun and the glow lamp. The lamps are now burning, and you see that we are able to produce electricity to our hearts' content. Downstairs there is a gas engine; the gas-engine is at work, the gas-engine works because the gas supplies energy which, stored up in the bowels of the earth in the form of coal for ages and ages, has been extracted; it has been converted into gas at the large gas works down the river Thames, it has been brought up here, it is burned in the gas engine, and produces energy in the gas engine exactly in the same way as the mutton or beef produced energy just now. There is a dynamo downstairs exactly like the dynamo that we have upon the platform, and the current that is produced is exactly as the current we just obtained, and is sending electricity through all the lamps in this room. The currents of electricity passing through the lamps are producing intense heat, the heat is producing the incandescence of a fine carbon filament, such as I will show you directly, and the consequence is that we are now being

lighted in this room by the energy that unmistakably and undisputably arrived on this earth millions of years ago in the form of sunshine."

After describing the arc and incandescent or glow lamps, and with the assistance of Mr. Sellar, of the Brush Company, actually making one of the latter before the audience, the lecturer went on to say: "The form of lamp that is being made before us is of the ordinary size that we see used generally, but there are a great many different sizes of glow-lamps. For instance, here is a very small lamp; above me you will see, if I may call the small one a dwarf, there is a giant glow-lamp. It is a lamp invented by the Honourable Charles Parsons; it is made by the Sunbeam Lamp Company, of Gateshead, and is called the Sunbeam Lamp; it has the same proportion to an ordinary lamp that an ostrich egg has to a hen's egg, and the light from it is of equally large proportion, as you see now the current has been turned on to it. It gives a light of 400 candles, but it is rather too brilliant I see by your faces, and we will go back to our old friends of the ordinary size. There are also above us lamps of various sizes; there is a 5 candle, 10 candle, 16 candle, 20 candle, and a 100 candle lamp. Here also are a 50 candle Swan lamp, a 16 candle Swan, and an 8 candle Swan lamp. There are the ordinary 16 candle lamp: these are being burned from the Grosvenor Gallery. Here is a miner's lamp, which is supplied with a current by the Schanschiell battery, the same as I showed you at first, the peculiarity of this arrangement is that when the battery is turned upside down the light goes off, the zinc and carbons occupy one half of the cell, and the solution the other half, the zinc and carbons being at the bottom, and the battery is not excited unless contact is made with the carbons and zinc. Such a battery as this will maintain its lamp for 12 or 13 hours. There are several forms of the Schanschiell battery. Here is a portable form, and lamp connected with it by a flexible wire, which can be used when travelling; or in the night, when you want to know the time, you can have a lamp and battery like this by your bedside, and you can turn it upside down, and produce a light, see the hour, and turn the battery back.

"These glow lamps are used for different purposes and ways. They may be used with care, they may be used recklessly; their duration depends a great deal upon the care with which they are used. A practised eye, one who is accustomed to deal with electric lamps, can tell at a glance when the lamp is raised to a proper incandescence, but there is a point in all lamps that is a sign of danger, and indicates 'breakers' (or breakage) ahead. Whenever in an electric light installation a glow lamp begins to show a blue effect, then breakers are ahead, the current must be reduced or other steps taken. I want to show you this blue effect, which is extremely pretty, and I want you to see the gradual stages through which a lamp passes, from long life to death, or rather to a very short and merry life. We can make the life of a lamp just exactly what we like: we can make a lamp last a minute, or we can make it last 100 years, and the number of years of its duration is simply dependent upon the current employed. I have here a glow lamp, and I pass a current through it. There is no blue effect at present; the current is increased and the carbon filament is raised to a high state of incandescence. In such a state it would not last for a long time, not more than ten minutes or a quarter of an hour; but it does not show the blue effect yet. On further increasing the current the blue effect appears, though I doubt whether it is visible to many of the audience; a little more current is put on, and the blue effect is very marked, the globe itself looks very brilliant, and, there the current has been increased until the filament has parted.

"It is always better when making an observation or experiment to know what you are going to see, so that you can direct your attention to exactly what is being done or to what you want to know. If I put another lamp through the same experiment you will be better able to understand this blue effect, and see just that point where the lamp is about to give out. The current is now on, and is being gradually increased, the lamp is now intensely blue—there, it has gone in the same way exactly

as the other one did. The way in which lamps burst is sometimes very beautiful: they disintegrate, they seem to volatilise, and the substance of the lamp is projected with great force against the side of the globe. On the table there are several beautiful specimens showing this effect.

"The glow-lamp in process of manufacture before you is now being unsealed from the pump; it is now exhausted, and we will pass a current through it so as to raise it to incandescence. The current is now on, and you see the lamp burns with full brilliancy. The next experiment is rather a cruel one, because it is wilful destruction. I will not destroy the lamp that has just been made before us, for I will keep it as a memento of this evening. I want to show the safety of the electric lamp. Many people imagine that there is a great deal of danger about it. I will take a handkerchief, and in it place a lighted lamp, when, on the globe being broken the carbon filament instantly goes out, and there is no damage to the handkerchief, or the slightest appearance of scorching or heating upon it. On breaking that lamp you heard a report. That is due to the vacuum, which, on sudden rupture, the air rushes in to fill. These lamps will not only burn in air, but will actually burn in water. Here I have a lamp which on placing in a bowl of water continues alight in the water just as well as in the air. You can imagine what an immense boon that is to our divers and others who unfortunately have to work under water for our benefit.

"I will not attempt to occupy your time in speaking of the beauties of this wonderful light, how it removes really poison from our air, how it is very good for sore eyes, because it burns with such steadiness that those who work under it really never find, in any shape or form any inconvenience or discomfort to the eyes. It is extremely clean; it does not fill the air we breathe with noxious fumes. People are little aware of it, but it is a very simple calculation to show that thirty gas-burners produce a gallon of water in an hour, so that if you have thirty burners in a shop, for instance, alight for six hours, six gallons of water are produced, and the water can very often be seen running down the cold windows of shops. That water absorbs sulphur and sulphuric acid, and when deposited on books and decorations destroys them. If we could only get the electric light cheap, delivered at our doors, then everybody who has an idea of luxury and comfort would at once take it."

CORRESPONDENCE.

DR. O. LODGE ON MODERN ELECTRICITY.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: Whether static electricity is associated with imaginary kinetic vortices in magnetism; or whether "electricity in radiation has anything to do with wave velocity, wave lengths," &c., &c.; or whether heat cannot be conveyed by radiation; these and many other points in the extended treatment may well justify being questioned; but on this occasion I desire to confine myself to a few points briefly, which may be of interest to any ordinary student of electricity.

The section on "Conduction in Metals," is hypothetical when compared with my carefully reasoned exposition (*Electrician*, July 22, 1887), where the facts observed may be thus summarily condensed:—

- 1st. That an opposite binary motion subsists in the wire.
- 2nd. That under all circumstances, the metal loses an atom or ion for every atomic change or unit of current, while at the other end an atom or ion of E or something (whether it will be matter or force) is correspondingly lost or given up.
- 3rd. That as these ions cannot pass through each other, they must do so spirally, and so produce the known inductive effects at right angles to every current, whether it be metal or fluid.
- 4th. That this friction of the moving particles must produce heat, as all or any friction does.

Now let any independent thinker compare this brief statement with the lengthened reasoning and varied hypotheses of the text.

The section "Conduction in Liquids," comprising four columns, is tedious, complex, and very hypothetical, compared with the treatment referred to, viz., that the liquid circuit is simpler, and more easy to understand, inasmuch as we have nothing to do with the unknown E, whose only known elements or ions are observed, and using the terms + H and - O in a representative sense, it is plain that for every atomic action or unit of current that O is lost on one side, precisely as H is lost or given up at the opposite end, and as in the metal, so here the inductive effect is a spiral or circular one.

Having said this we have said all, but as the subject has been so inextricably mixed up with kinetic and electric hypotheses it may be well to moot a few comparisons.

1st. If the opposite progression of + and - ions took place side by side, as *opposita*, then their inductive effects would be lateral in a flat sense, whereas we know it to be so different, and we also know that a + current going in one direction and a - current in the opposite direction are only different expressions for the same thing.

2nd. All the hypothetical propositions about the ions carrying different charges of electricity are utterly superfluous, a grandiloquent talking about things of which absolutely nothing is known, whereas the inductive properties of known elements, or ions, is something actually known and easily understood. Why, then, should our knowledge of these properties be obliterated or ignored in order to introduce occult or imaginary charges to accomplish that for which the ions are so manifestly fitted?

3rd. As to the different valency charges of electricity, it is a fashionable hypothesis that the ions travel at different rates; "for each of these atoms in the free state possesses a charge of electricity: the H atom a certain amount of + electricity; and the O twice as much - electricity; and hence they travel at different rates."

Of course all this confusion comes of our mistaken modern chemistry; but the great French chemists, and many others, have never bowed to this delusion. They know that O = 8 is electrically and chemically the true equivalent of H = 1, or Cl = 35.5, &c., and that this is patent in a thousand chemical ways.

In the section "Condition of the Medium" the following distinction does not indicate clear views. "The induction of static electricity is an electrostatic strain; that of current is an electrokinetic strain."

But I think the doctor is too clear not to see otherwise than, as the former is a static strain, so current induction is no less essentially static, so long as equality of current subsists. Both equally vary under varying conditions, but in the section "Energy of Current," the whole secret of previous mystification comes out, and the seat of electric or propulsive energy is not where the chemical action takes origin, but somewhere mysteriously or kinetically all along the circuit, and not in the metal or conducting circuit, but in the surrounding medium.

May we be forgiven if we refuse to follow into such long and devious paths, ending in a vast wilderness of mathematical maze? Life is too short and time is too precious, while the simple truths of nature are so specially attractive and inviting.

But just one word on the section "A Voltaic Battery." We read between the lines most of the simple facts referred to, but the sins of omission and commission deserve a passing notice.

1st. That nothing is said as to how these opposite ions pass each other, and far more important still, nothing is said of the inductive functions of the transit or current, yet these are among the most ordinary or A B C facts of common observation.

2nd. The detailed facts are mixed up with interminable if not blinding considerations of extraneous hypothesis.

One is the fashionable idea that the ions are in a beautifully kinetic sense, "either actually dissociated, or so frequently changing (partners) at random, from molecule to molecule, that the direction of their motion may be guided by a feeble force." Prof. Poynting has shown, on the principles developed by Maxwell, "that the battery models should not have a source of power at one place; but that it should

T¹, passes thence to the top of the spring, then down the spring into the movable coils C¹, from there to the steel cup E, through the contact point to the iridium tipped steel pivot, from that through the fixed coils, and so back to the other terminal, T. The windings of the movable coil are so arranged that it is static, and not influenced by a vertical or horizontal uniform field. This is important in an instrument to be used in the neighbourhood of powerful magnets.

The movable coils carry a light aluminium needle, Q, which projects up through a slit in the dial plate, opposite to the zero of the scale.

The whole instrument is contained in a small wooden box, about 4½ in. square by 3 in. deep. On opening the box a dial plate is seen having a circular scale divided so that the volt readings are obtained without any calculations. The operation of taking a reading is as follows: The box is first levelled on the table by means of a wooden wedge provided for the purpose,

FIG. 4.

The central hollow boss is first turned until the mica index finger is at the zero of the scale. The aluminium index carried by the movable coils, which projects up through a slit in the dial, should also be opposite the zero. If this is not the case the mica index finger has to be shifted. This is accomplished by slackening up the milled head on the top of the central boss and re-adjusting the index until the mica index finger and the aluminium index of the movable coils both stand opposite to each other at the zero. The current is now passed, and the electro-magnetic action causes the movable annular coils to be shifted along the fixed coils, displacing the aluminium index. The central boss, carrying the upper end of the spring, is then turned until a torsional force is brought to bear on the movable coils, bringing them back against the electro-magnetic forces into the zero position. It will now be found that the upper end of the spring will have been twisted

FIG. 5.

through a certain angle, as indicated by the position of the mica index finger. The value of the current passing through the instrument is proportional to the square root of this twist required to bring back the coils into their zero position, and, as the force brought to bear on the coils is proportional to the angular displacement of the upper end of the spring, it follows that the square root of the angular displacement of the mica index finger required to maintain the movable coils at their zero position is proportional to the strength of the current flowing through the instrument. To avoid any calculations or reference to square-root tables, the dial is graduated in the following manner: If the instrument is intended to read, say, from 20 to 110 volts, then one complete turn, or 360 deg. displacement of the index, is required to balance the electro-magnetic force due to 110 volts

on the terminals of the instrument. The angular displacement for x volts is, then, $\frac{360 \times x^2}{(110)^2} = \frac{18}{605} \times x^2$, measured in degrees,

and accordingly the positions for all volt values from 20 to 110 can be set off directly on the dial. The index needle is then simply turned until the aluminium index is brought back to zero, and the dial reading gives at once the volts. This form of graduation has the advantage that the scale interval corresponding to one volt is greatest in that part of the scale which will be in each instrument presumably most used.

In order to render the instrument portable, means are provided to raise the movable coils off the point P by the action of closing the box. A clutch-bar, K, is so arranged and pivoted, that by means of a pin, R, sliding in a hole in the box a pressure on the upper end of this pin (H, Fig. 1) raises the coils, C¹, and relieves the iridium point of the pressure of the movable coil-bar.

It is not desirable that the movable coils should be taken up and let down suddenly on the pivot, and to make this action deliberate the box lid is opened and closed by a screw. The user is thereby compelled to open the box slowly and let down the coils with a gentle motion on to the pivot P.

The voltmeters are constructed to work over various ranges. One type ranges from 20 to 110 volts. By associating a resistance coil with the voltmeter, the resistance of which is equal to that of the voltmeter, the volt values of all the readings become doubled and the instrument becomes available for use between 40 and 220 volts. In order to give a little margin over and above the 110 and 220 volts, the graduation is continued, according to the square-root law, along an outer circle. A little more than one complete twist of the spring enables a reading to be taken up to 115 or 120 volts on the 110 volt instrument, or to 230 or 240 on the 22 volt instrument. In the 110 volt instrument (construction A), the following are the electrical and mechanical data of the instrument: The weight of the movable coils complete is in all 20.27 grammes. The number of turns of wire is 960, on both coils together, and the total resistance is 300 ohms. The four fixed coils have each 840 turns of wire, or 3,360 turns in all, and a resistance of 1,200 ohms. The total resistance of the voltmeter is therefore 1,500 ohms. The temperature-resistance variation coefficient has been carefully determined for a mean temperature between 15 deg. and 30 deg. C. for the particular kind of German silver wire used, and it is .0273 per cent. per degree. Accordingly, as far as regards change of temperature as a whole, it requires an alteration of 30 deg. C. to make a change of 1 per cent. in the value of the voltmeter readings. To prevent, as far as possible, heating of the coils, each voltmeter is provided with a key. In using the instrument the first operation after opening should be to level it carefully, by inserting, if necessary, the wooden wedge provided under the front or back side until the pointer on the movable coils swings freely from side to side.

(To be continued).

ELECTRICAL MEASUREMENTS, ESPECIALLY AS APPLIED TO COMMERCIAL WORK.*

BY PROF. WM. A. ANTHONY.

The lecturer was introduced by Prof. Edwin J. Houston, as follows: Ladies and Gentlemen.—We are fortunate this evening in having with us one well known in electrical circles in this country. Indeed, so well and favourably has he been known as a practical electrician, that he has been induced to leave a position which he has for so many years held with distinguished success. I take pleasure in introducing to you Prof. Wm. A. Anthony, formerly in charge of the Department of Electrical Engineering in Cornell University, and now consulting electrician of the Mather Electrical Company.

PROF. ANTHONY: Mr. President, Members of the Institute, and Ladies and Gentlemen.—The subject I have chosen for this evening's lecture is one of the driest that could well have been chosen, but I have believed it to be of sufficient importance to warrant its presentation to an audience such as I suppose would be attracted to the Franklin Institute meetings. Thousands of men and millions of capital are to-day interested in the applications of electrical science. We have come to a point where haphazard work is no longer admissible, where electrical currents must be gauged and measured, where the electrical properties of materials must be accurately determined; where, in short, machines and apparatus must be built to a gauge, and their products measured electrically as well as mechanically. As in mechanical construction we have gone beyond the use of the foot rule and carpenter's square, and are fixing our dimensions by standard gauges to the ten-thousandth of an inch, so in the electrical construction we have gone beyond measurements by rude and imperfect instruments and have got to a point where, if our machines and apparatus are to find their place in the

* Abstract of a lecture delivered at the Franklin Institute.

markets of the world, we must gauge our work by accurate electrical standards.

What are the electrical quantities we have to measure? Before attempting to answer this question let us consider for a moment the origin of the terms we shall have to use. Our electrical nomenclature has been derived from the fluid theory of electricity. We talk about an electrical current as though something were flowing, we talk about quantity of electricity as though we considered it something to be weighed or measured; we talk about capacity for electricity as though a body could be filled with and hold a certain quantity of it, as a vessel may be filled with water. Whence comes the idea of an electric flow?

If we go back to the early electrical experiments where insulated bodies were "charged" and then discharged—the electricity drawn off, as it were—by a wire connecting the insulated body to the earth, we see that the idea of something accumulated in the body and then conveyed away by the wire was a very natural one, and when we found that the wire was heated, the passage of something through it seemed to be proved. Then came the voltaic battery and the evidence of greater and greater effects as the cells in series were increased, a close analogy to increasing pressure causing a more rapid flow of fluid. It was seen that many cells in series gave power of overcoming obstacles, that insulation had to be more perfect to prevent escape. Hence the terms high tension and low tension, as these were applied to gases.

There is some misapprehension among those who have had only a practical acquaintance with electrical phenomena, and do not know the fundamental principles. I hear a great deal of talk about high tension currents and low tension currents, as though the currents themselves were different. It should be understood that a current of one ampere is always a current of one ampere, always conveys one coulomb per second whether the tension be high or low, just as a stream that conveys one gallon of water per second, is the same stream whether under high or low pressure. The term tension is a misnomer as applied both to electricity and to gases. Pressure is the proper term for gases, and may be used by analogy for electricity. Potential is the scientific term for the electrical condition for which the word tension has been used. We can best understand it by drawing the analogy between it and fluid pressure. We find in the evening that the gas is burning dimly. We say at once, too little pressure in the mains. If more pressure is put on, more gas is forced through the burners and our lights burn more brightly. If our incandescent lights burn dimly, it is a lack of potential. Let the potential in the wires be increased, more electricity is forced through the carbon filament with an improvement in the light. It is not the greater pressure that gives you the brighter gas light, but the larger quantity of gas that the greater pressure supplies. So it is not the increased potential that causes the increased brightness of the carbon filament, but the greater flow resulting from the higher potential.

The electrical quantities we wish to measure are then *quantity*, which is measured in units called *coulombs*, and may be considered as analogous to pounds of a gas or liquid—*potential*, measured in *volts*, analogous to pounds per square inch of fluid pressure; *capacity*, measured in *farads*, analogous to cubic feet of a vessel for holding fluids, and *strength of current*, measured in *amperes*, for which there is no close analogue in fluid measurements.* Yet in electrical measurements, strength of current is, perhaps, most important of all, and furnishes the fundamental unit of the system. Another quantity of great importance in electrical measurements is the *resistance* of bodies to the flow of electricity. It is measured in *ohms*, and may be compared, qualitatively, to the frictional resistance which fluids experience in flowing through pipes.

Let us consider now these several quantities and their relations to each other, from the standpoint of the analogy of a flowing fluid. Here is a pipe carrying gas. We wish to know how much gas is flowing through it per hour or day or month. This the gas meter professes to tell us, but there is sometimes a question whether its statements are truthful. We could run the gas into a suitable vessel and measure it, but that would be inconvenient in the practical use of the gas because we consume it as it flows. But whatever method we use our object is to determine the total quantity of gas delivered in a given time, and not the rate of flow at any instant. By *rate of flow* I do not mean the velocity of the gas, but the rate as indicated by the quantity of gas flowing in unit time when the flow is uniform. In this sense, when the same quantity of gas per minute is flowing, the rate of flow is the same whatever the size of the pipe. But there is no important effect of the gas dependent upon the rate of flow. The pipe that conveys it acquires no new properties or powers. In fact, no effect is produced by it that would indicate to us whether the gas were flowing or not. To be sure, heat is generated by the friction of the gas, but in practice this is too small to be perceived and is of no consequence. Moreover, the heat generated is a function of the velocity of the gas, and not

simply of the rate of flow as I have used that term. We have, therefore, no need to know the rate of flow of a gas, we make no attempt to measure it directly, we have no unit in which to express it, and no distinctive name for it as a quantity.

Now let us compare an electric flow. Here is a wire conveying an electric current. We know there is something going on it because we see the effects on beyond, just as we know that gas is flowing in this pipe because we see it burning in your gas burner. As with the gas, we can determine the quantity of electricity flowing in a given time by measuring its effects. Electricity flowing through acidulated water generates hydrogen and oxygen gases. The quantity of these gases generated in a given time may be taken as a measure of the total amount of electricity flowing. Electricity flowing through a solution of a metallic salt, as copper sulphate or silver nitrate, deposits the metal. The weight of deposited metal will measure the total flow. But these methods, like the methods of measuring gas, tell us only the average rate of flow, and not the rate at any given time. But a conductor conveying electricity, unlike a conductor conveying fluid, exerts forces due to the current in it. This wire will deflect a magnetic needle, will attract iron filings. (Shown by experiment.) In short, it develops all around it a magnetic field.

This effect of an electric flow is of such great importance and finds such a multitude of applications, that the rate of flow upon which it depends is a more important element than the total quantity flowing, and the unit in which we measure it, the ampere, is based upon this magnetic effect. This unit has taken its place with our foot, and pound, and gallon, and is making its way very rapidly into the popular vocabulary. Notwithstanding the fact that it is coming into such general use, there seems to be a great deal of confusion as to what an ampere is. It seems to me important that the true definition of this unit current should not be lost sight of, and I wish to protest against the admission of the arbitrary definitions that are finding their way into electrical literature.

The true ampere is based upon the absolute unit current as defined by the British Association committee. The absolute unit current is that current, a centimeter length of which will produce a unit magnetic field at a centimeter distance, or it is that current which when flowing in a conductor bent into a circle of one centimeter radius, will develop at its centre a magnetic field of intensity 2π . This is the foundation of the electro-magnetic system of electrical measurements. Upon this unit are based all the other units of the system. The ampere is *one-tenth of this unit*. This was the value of the weber, the former name of the unit of current, and the Paris congress, in changing the name to the ampere, did not change its value, but expressly voted that this should continue to be its signification.

Now to measure an electric flow in amperes. We may bend the conductor into a circle and compare the field produced at the centre of the circle with some known magnetic field, such as the magnetic field due to the earth. This is accomplished by means of the tangent galvanometer. The conductor, of one or many circular convolutions, is placed with its plane in the magnetic meridian; in this position the force it produces is at right angles to the earth's magnetic force and a little needle placed at the centre of the circle will take a position depending on the ratio of the two magnetic fields. If the needle stands at 45 deg. with the magnetic meridian, the two fields are equal, and, in general, the ratio of the field produced by the current to that of the earth is the tangent of the angle that the little needle makes with the meridian.

In the great tangent galvanometer of the Cornell University, this method is employed to measure currents up to 300 amperes. The great difficulty in this method is that the earth's magnetic field is not constant, but varies from day to day and from hour to hour. In all work where accuracy is aimed at, the horizontal intensity of the earth's magnetic field must be determined at the time of making an observation for current. In the Cornell instrument a coil suspended by a wire serves to determine the horizontal intensity by balancing the force developed by a current in the coil in the earth's field against the force of torsion of the suspending wire. But another and more serious difficulty is met with when any attempt is made to use this method for ordinary practical work. The earth's magnetic field is greatly affected by the presence of magnetic substances. A small mass of iron is sufficient to change very greatly the value of the earth's field in its vicinity. A large magnet or a dynamo may at many feet distance change the earth's field by a hundred per cent. The tangent galvanometer can only be used therefore where there are no disturbing causes. It cannot be used in a dynamo station or in a workshop. But in a suitable place it is invaluable as a standard with which to compare other instruments. The Cornell tangent galvanometer is mounted in a special building, constructed entirely without iron, and placed at a distance from all other buildings. The earth's field there is subject only to such changes as are due to natural causes, and with the appliances for determining these changes the highest class of work can be done.

{To be continued.}

* The rate of flow, say in gallons per minute, of a fluid in a pipe, is a quantity of fluid passing, divided by time, is a rate analogous to $E \div F \div E$.

FORTHCOMING BRUSSELS EXHIBITION.

MEETING AT THE MANSION HOUSE.

A meeting of exhibitors in the British Empire Section of the International Exhibition of 1888 was held at the Mansion House on Tuesday.

The **Right Hon. Polydore de Keyser** took the chair at 3 p.m.

The **Chairman**, in opening the proceedings, said he had received a letter from the president of the exhibition asking him to support Mr. Bapty in forming a committee in London to promote the interests of this exhibition.

Mr. S. Leo Bapty, Commissioner General for the British Empire Section, said the scheme took root early last year, and a committee of Belgian manufacturers and merchants had been formed under the presidency of the Count of Flanders. The International Exhibition now proposed was the first that had ever been held in Brussels, and it had the hearty support of the King and Government. The site selected covered over 100 acres, and was situated in the best part of the city. The grounds in connection were beautifully laid out. He had been to Brussels to consult the committee as to a British section, but found the prices for space were so high that after consideration it was decided to have a separate building, which is now being erected. When he told them this building formed part of the main structure of the Manchester Jubilee Exhibition he was sure they would agree with him that it was well suited for the purpose intended. In response to invitations he had issued, a number of noblemen and gentlemen had consented to be placed on the committee, including the Marquis of Derby, Latham, and Aberdeen, Lord Vivian, Lord Chas. Hamilton, M.P.; Sir R. Samuelson, M.P.; Sir R. N. Fowler, M.P.; Captain Sir Douglas Galton, Sir Frederick Abel, Sir J. C. Lee, Sir G. H. Chubb, Sir H. Grubb, Sir James King, Colonel E. S. Hill, C.B., M.P.; Lord Provost of Glasgow, Mr. J. Corbett, M.P., and the Mayors of Birmingham, Leeds, Liverpool, Manchester, Newcastle, and Sheffield.

A resolution was passed thanking the Lord Mayor for consenting to become President of the Section.

In response to the vote of thanks, the **Lord Mayor** said he thought that the movement would do good to the commerce of this country, and also benefit Brussels, in which city he took a warm interest.

Mr. Bapty said the time for receiving applications for space had been extended to the 15th of February.

LEGAL INTELLIGENCE.

TELEPHONE WIRES IN THE CITY.

In Queen's Bench Court I, there was heard on Wednesday the case of Smart, Black and Company v. United Telephone Company. This was a motion for a new trial on behalf of the defendants, the jury at the trial before Mr. Justice Mathew having given a verdict for the plaintiffs, with damages. The action was brought by a firm of importers of Swiss embroidery and haberdashery, carrying on business in the City, to recover compensation for injury to their stock, caused, as they alleged, through the fall of a telephone wire belonging to the defendants, which was stretched across the roof of their warehouse, and which fell during the great snowstorm of Christmas, 1886. It was alleged that the wire in falling swept the snow off a portion of the roof, and caused a gutter to give way, in consequence of which, when the thaw came during the Christmas holidays, snow water entered the plaintiff's premises and damaged their stock. On the other hand, defendants contended that the falling of the wire had nothing to do with the breaking of the gutter, which was due to the weight of the snow. Their Lordships refused a new trial.

COMPANIES' MEETINGS.

EASTERN TELEGRAPH COMPANY (LIMITED).

The 31st half-yearly general meeting of the Eastern Telegraph Company (Limited) was held on the 19th inst. at Winchester House, Old Broad Street, E.C.

Sir John Pender, K.C.M.G., presided, and, in moving the adoption of the report, observed that the revenue for the half year ended September 30 last had been £291,265, being a decrease of £964 as compared with the revenue for the corresponding period of 1886. The directors considered that satisfactory, because the large decrease of revenue caused by the reduction of the tariff to India was sensibly diminished, and, indeed, the improvement in traffic with Australia, China, and other countries in the Far East had more than recouped the loss on Indian messages. Their traffic with Egypt, on the other hand, showed a further falling off, but that had been made good by an increase of messages exchanged with Portugal and South America. For the current half year their prospects were most favourable, and it was hoped that next July, when they presented the accounts for the financial year to March 31, they would be able to give the shareholders a small bonus in addition to the 5 per cent. dividend. The total working expenses of the half year had been £79,536 being a reduction of £1,085. The general expenses in London had been £3,012, or £46 more, and at the stations the expenses had been £56,386, or a decrease of £1,743. The principal reduction, however, had been in repairs and renewals of cables, which had cost £34,102, or £19,863 less than in the corresponding period of 1886. After paying all expenses and providing for *debt* and preference interest, they were able to pay an interim

dividend on the ordinary shares at the rate of 5 per cent. per annum, and to carry forward £29,397, or £16,306 more than at the same date in 1886. That was a considerable sum, but until they closed the year there was always an amount of uncertainty as to whether the sum carried forward would be materially reduced by interruptions to the cables. At the last meeting he referred to the difficulties they had had with the French Government in connection with the renewal of the Company's wire through France. That privilege would expire next year, and though they paid a good deal of money to the French Government for it they had not yet been able to get a renewal. They had, however, laid a fresh cable from Portofino to Lisbon, Gibraltar, Malta, and Zante. It was working in the most satisfactory way, adding them in carrying their traffic, and it had placed them in a perfectly independent position if war broke out on the Continent at once. He referred at the last meeting to the improvement in trade, and he was glad to say that the improvement was still continuing. They had now all but recouped the amount of money which they had been compelled to give up at the Telegraph Conference at Berlin, and he hoped they would now be enabled to resume paying their old bonus of 1 per cent. If they had kept their reserve fund intact and had their new cables out of capital their reserve fund would now stand at over £1,000,000, instead of at £576,000. They had, however, instead of borrowing capital for the purpose, preferred to draw on the reserve fund and on current income. He congratulated them on the prosperous condition of the Company.

The Marquis of Tweeddale seconded the motion.

Mr. L. Nicholson inquired whether there was a prospect of the cable being dedicated to the Philippines, a very important Spanish possession. He afterwards moved a motion to the resolution cordially congratulating the chairman on the recent honours which had been conferred on him by the Queen.

Dr. Waller seconded the proposal.

The motion, with the addition of the rider, was unanimously adopted.

The **Chairman** warmly thanked the shareholders for the kindness which they had invariably shown him. If he were to relate the history of submarine telegraphy he would have to mention the names of a great many who had been associated with him, but he could not refrain from alluding to the eminent services of his colleague, Sir James Anderson. With regard to the question asked by Mr. Nicholson, the Eastern Extension Company were now in negotiation with the Spanish Government on the subject.

The retiring directors and auditors were then re-elected, and the meeting terminated.

DIRECT UNITED STATES CABLE COMPANY.

The 21st ordinary general meeting of the Direct United States Cable Company was held on Friday, the 20th inst., at Winchester House, Old Broad Street, E.C.

Sir John Pender, K.C.M.G., presided, and in moving the adoption of the report observed that the revenue for the half year, after deducting out-payments, had been £25,003, and after paying working and other expenses a balance of £7,158 remained as the net profit of the half year. That was at the sixpenny tariff. The balance of £7,158, with the addition of £5,004 transferred from the reserve fund account—out of interest received on the investments—made a total of £12,162, which had been appropriated in paying the dividends of 2s. each for the quarters ended June 30 and September 30 last. A dividend of 2s. a share for the quarter ended the 31st ult. had been declared, and would be payable on the 24th inst. The revenue at the sixpenny rate showed an increase of £3,399 as compared with the corresponding period of 1886, when the tariff was the same, but the progressive development in the traffic carried during the first half of 1887 had not been maintained. The expenses in London had been £456 less, but at the stations the amount had been £130 more. It was satisfactory to note that, notwithstanding the large traffic carried, and some additional outlay incurred through the action of the French Company, their total working and other expenses during the half year had been less than in any previous half year of the company's existence. The item of cost of renewing their cables and station to Halifax remained for the present in the balance sheet. Their investments continued to be worth much more than the company had paid for them. At their last meeting he expressed his belief that the sixpenny tariff would not be a permanent rate, but he stated at the same time that while the development of the traffic was going on, it would be a misfortune to make any change. They had, however, now arrived at a point when the sixpenny rate seemed to have ceased to bring an increase in the returns, and, therefore, the opinion he expressed at the last meeting as to the mode of dealing with the question he now entirely endorsed. The Western Union Company had taken an active part in the effort to settle the war of rates, and they had adjusted the land charges in a way which, he believed, was now working satisfactorily. That company had also acquired the control of the Baltimore and Ohio telegraph system. There had been some negotiations in America between Mr. Gould and Mr. Mackay, and they had been referred to this country, but the proposals were of such a nature that they could not be entertained. Had they accepted the proposals they would have been positively guaranteeing a very high rate of interest to a company which had had cables that were not wanted, and, in short, it would have been giving a very high premium to that company. Speaking, he believed, with the full concurrence of his Board he would be very pleased to see a conference of the different companies held to consider the question of what would be a fair rate both for the shareholders and the telegraphing public. The suit which the Anglo-American Company had brought against the French Company for seceding from the pool had ended—at least, the decision for the time being was in favour of the Anglo-American Company, who had been awarded damages to a considerable amount. He could not say whether the deep-

one would be sustained on appeal, but he believed if the directors of the French Company, instead of appealing to the courts of law, appealed to the English directors as to meeting together and trying to bring about a more satisfactory result, it would be much better for telegraphy generally, and for telegraphists all the shareholders. He made that remark with all respect and respect for the directors of the French Company, from whom he would be glad to receive a communication on the matter. He was not prepared at that meeting to say definitely what the rate should be, but if they could maintain the present traffic at a shilling per mile it would not be a burden to the telegraphing public and the rate would be much more satisfactory to the shareholders. Referring to the transfer of the cables and station from Tisbury to Halifax, and to the removal to the southward of Brown's Bank of the short cable which had previously run across the bank, he expressed a hope that by co-operation they would in future be saved considerable expense. The directors prepared, being at Halifax, to carry their cable on to have a short cable the Government desire them to do so.

Mr. William Ford seconded the motion.

In the discussion which followed, Mr. Griffith and Mr. John Newton suggested the chairman on the honours which had recently been conferred upon him by the Queen. A hope was expressed that the vacancy at the Board would not be filled up, and Mr. Gosden and Mr. Wilberby thought that the directors might, in existing circumstances, give up a part of their fees.

The Chairman, in reply, stated that for the present the directors did not intend to fill up the vacancy at the Board which had been caused by the death of Lord Huxley. The agreement between the Company and the Anglo-American Company was very beneficial, and would last for many years. The directors, under the articles of association, were entitled to 25 per cent. more for fees than they had taken. It was not to work at the present time very hard. It would be most kind of them to trench on the reserve fund proper, in order to cover this increase.

The motion was then agreed to.

PROVISIONAL PATENTS, 1888.

JANUARY 13.

- 540 Improved electric balloon pleasure carriages. Thomas Needham, Park House, Fitzwilliam street West, Huddersfield.
- 549 Improvements in dynamo-electric generators and motors. James Blackburn, 33 Chancery-lane, London, W.C.
- 584 Improvements in the method of and apparatus for supplying electric railways or tramways with electricity. William Leonard Madgen, 28, Southampton-buildings, London, W.C.

JANUARY 14.

- 606 Improvements in apparatus for determining the poles of electrical circuits and generators of electricity. August Bachmann, 38 Alexander Str., Berlin, Germany.
- 683 Improvements in thermo-electric elements and piles. Robert Jacob Gilder and the Firm of Louis Pintsch, 28, Southampton-buildings, London. (Complete specification.)
- 683 Improvements in dynamo-electric machines. Carl Geisler, 15, Southampton-buildings, London. (Complete specification.)

JANUARY 16.

- 686 Improvements in internal combustion thermo-dynamic engines. James Hargreaves, 4, Clayton-square, Liverpool.

JANUARY 17.

- 698 An improved holder and switch for electric lamps. Robert Genthwaite, Sunbridge-chambers, Bradford, Yorkshire.
- 706 The telephone, consisting of a mouthpiece to be attached to the transmitter. Leo Eugene Percy, 9, London-street, Southwark, London, S.E.
- 713 Improvements in voltaic or galvanic batteries. Theophilus Cook, 10, Thorne-terrace, Thorne-road, Forest Gate.
- 718 Improvements in self-acting electric batteries or generators in which the liquids are automatically renewed. Emil Garton, 47, Lincoln's Inn-fields, London. (Marcel Supper, France.)
- 727 Improvements in thermo-dynamic electric machines. Rankin Kennedy, 95, Buchanan-street, Glasgow.
- 729 Improvements in electric batteries and elements therefor. David Urquhart, 47, Lincoln's Inn-fields, London.
- 734 Improvements in galvanic batteries. James Nead, 321, High Holborn, W.C. (Complete specification.)
- 742 Improved apparatus for tanning hides and skins by the aid of electricity. Lorenz Albert Groth, 3, Tokenhouse-lane, London.
- 750 Improvements in and relating to electric railways and to vehicles for use thereon. Henry Harris Lake, 45, Southampton-buildings, London. (David Gustavus Weems, United States. — Complete specification.)

JANUARY 18.

- 785 Improvements in the construction and application of transformers for the distribution of electricity for lighting and other purposes. John Augustine Kingdon, 29, Marlborough-st., London, N.W.
- 791 Improvements in junction boxes for electric conductors. Ronald Augustus Scott, 331, King-street, Hammersmith, London, W.

- 804 Improvements in electric clocks. Martin Pulvermann, 4, South street, Finsbury, London. Carl Bohnmeyer, Germany.

JANUARY 19.

- 875 Electric igniting apparatus. Leon Hen and Rudolphe Weinmann, 28 Southampton-buildings, London, W.C.
- 874 Improvements relating to the repair of electric incandescent lamps. Frederick Henry Jackson, 77, Southwark street, and William John Woodward, Jackson's Electrical Works, Ever-street, Southwark, Surrey.

COMPLETE SPECIFICATIONS ACCEPTED.

JANUARY 13, 1887.

- 563 An improved dynamo-electric machine. Henry Harrington Leigh, 22 Southampton-buildings, Chancery-lane, Middlesex. Jean Louis Clery, France.

JANUARY 15, 1887.

- 701 Improvements in electrical motors. Sebastian Ziani de Ferranti, 5, Stanwick road, West Kensington, Middlesex.
- 702 Improvements in dynamo-electrical machines. Sebastian Ziani de Ferranti, 5, Stanwick road, West Kensington, Middlesex.

JANUARY 17, 1887.

- 717 Disc dynamo-electric machines and motors. William Brooks Sayes, 24 Glynsa road, Laverham Hill, London S.W.

FEBRUARY 25, 1887.

- 2959 A new or improved combined bell-push and automatic switch for electric alarms. Hippolyte Charles Choquet, 18, Buckingham street, Strand, London, W.C.

MARCH 9, 1887.

- 3606 Improvements in simultaneous telegraphy and telephony. Charles Selden, 55 and 56, Chancery-lane, Middlesex.

MARCH 15, 1887.

- 3878 Improvements in or connected with electric alarm clocks. Henry Beardman, 20, Charles-street, Bradford, Yorkshire.

MARCH 16, 1887.

- 3943 Improved instruments for measuring electric currents. William Henry Douglas, 7, Cherry street, Birmingham.

MARCH 19, 1887.

- 4138 Improvements in safety devices in electric circuits. Arthur Cecil Cockburn, 25, Petherton road, Canonbury, N.
- 4153 An improved mechanical telephone. Thomas Harding Churton, Park chambers, 35, Park square, Leeds.

JUNE 10, 1887.

- 8329 Improvements in electrical signalling apparatus for railways. William Edward Langdon, Midland Railway, Derby.

SEPTEMBER 2, 1887.

- 11,923 Improvements relating to the manufacture of plates or electrodes for primary or secondary electric batteries and to apparatus therefor. Carl Ludwig Rudolph Ernst Meeres, 45, Southampton-buildings, London. Antedated 19th February, 1887, under International Convention.

OCTOBER 31, 1887.

- 14,768 Improvements in the construction of switches for the making and breaking of circuits conveying electric currents. Charles Mark Dorman and Reginald Arthur Smith, 24 Brazenose-street, Manchester.

NOVEMBER 28, 1887.

- 16,351 Improvements in electric belts. Alva Owen, 18, Buckingham street Strand, London.

NOVEMBER 29, 1887.

- 16,376 Improvements in electric arc lamps. Clarence Bingham Noble and Roland Dumas Noble, 36, Southampton-buildings London.

DECEMBER 13, 1887.

- 17,157 Improvements in galvanic batteries. Henry Harris Lake, 45, Southampton-buildings, London. James Orville Whitten, United States.

SPECIFICATIONS PUBLISHED.

1886.

- 12,032 Electric incandescent lamps. A Featherstonhaugh. 8d.
- 16,650 Electric apparatus for the control of watchmen. O. Skriver and F. Dyorak. 8d.
- 16,661 Self-regulating dynamo-electric generators. R. P. Sellen and others. 8d.
- 16,879 Printing telegraphs. W. S. Steeles. 8d.

1887.

- 266 Electric telegraphs. E. Edwards, Kunhardt. 1s. 6d.
- 3360 Train signalling on railways. S. T. Dutton. 8d.
- 16,120 Voltaic batteries. E. Tyer. 6d.
- 14,198 Obtaining light, motion, &c., by electricity. M. J. Roberts. 1s. 3d.

1878.

- 4847 Electric lamps. F. J. Cheesbrough. (Sawyer.) 11d.

CITY NOTES.

Western and Brazilian Company.—Mr. W. J. Andrews has been elected chairman of this Company in place of Sir Henry Drummond Wolff, who has resigned his seat at the board, and Lord Richard Howe Browne to a seat on the board to fill the vacancy.

Cuba Submarine Company.—The directors of the Cuba Submarine Telegraph Company (Limited), after providing for the dividend on the Preference Shares and placing £3,000 to the reserve fund, recommend a dividend on the Ordinary Shares at the rate of 8 per cent. per annum, tax free, leaving £972 to be carried forward.

United Telephone Company (Limited).—The directors have decided to call up the remaining amount payable in respect of their 20,000 new shares of £5 each (numbered 80,001 to 100,000), issued at £2 per share premium, viz., £2 10s. on account of capital, and £1 on account of premium. The call will be payable on the 1st of May next.

National Telephone Company.—At the meeting of the directors of the National Telephone Company (Limited), held on Wednesday, it was resolved to declare a dividend for the six months ending December 31st last at the rate of 6 per cent. per annum on the first and second preference shares, and an interim dividend at the rate of 4 per cent. per annum (as against 3 1/2 per cent. for the corresponding period last year) on the ordinary shares, and that the balance of £3,570 should be carried forward. The unaccrued revenue carried forward to the credit of next account amounts to £45,826, as against £38,722 last year.

Anglo-American Telegraph Company.—The directors of the Anglo-American Telegraph Company (Limited) recommend a balance dividend of 10s. per cent. upon the ordinary consolidated, and a balance dividend of 20s. per cent. upon the preferred stock for the year ending December 31, to be payable on the 4th of February, less income-tax, to the stockholders registered on the 16th inst. After paying the foregoing dividends there will be an estimated balance of £2,300 to be carried forward. The above dividends, together with those already paid, will amount to £1 7s. 6d. per cent. on the ordinary consolidated stock, and £2 15s. per cent. on the preferred stock for the year.

NOTES.

Juvenile Lectures.—The abstract of the second lecture has unavoidably to be held over to our next number.

Old, but very good.—"Tommy, my son, what is longitude?" "A telegraph wire, papa." "Prove it, my son." "Because it stretches from pole to pole."

New Firm.—We understand that Messrs. Appleton, Burtsey and Williamson have entered into partnership, and will immediately commence business as electrical engineers and contractors, at Balmoral Buildings, Queen Victoria-street, E.C.

Telegraphy in America.—It is reported that the petitions for government telegraphs, circulated by the Knights of Labour, are being returned to headquarters in Philadelphia with great numbers of signatures. A million names are expected.

Electric Traction.—At the meeting of the Northampton Tramways Company mention was made of the experiments being carried out on the West Metropolitan line, and a suggestion made that if these experiments proved successful electric traction should be adopted at Northampton.

The Telephone from Paris to Brussels and Amsterdam.—A third telephone line from Paris to Brussels is projected, and also, in connection with it, a line from Brussels to Amsterdam. Telephonic communication between Paris and Amsterdam would thus become possible.

Society of Telegraph Engineers.—The paper to be read at the ordinary meeting to be held at the Institution of Civil Engineers on February 9 is one by Mr. Gisbert Kapp, A.M.I.C.E., "On alternate current transformers, with special reference to the best proportion between iron and copper."

The Electric Light in Vienna.—According to the Electrotechnical Society of Vienna there are in this city and its suburbs 338 arc and 12,600 incandescence lamps in operation. This appears no inconsiderable figure when it is borne in mind that the commune of Vienna comprises but little over 10,000 gas burners.

Rather Abstruse.—According to *l'Electricien*, M. Felix Lucas has succeeded in the electrical determination (sic) of the real and imaginary roots of the derivative of any polynomial, by assimilating the curves of level or *cassinoïdes* to the equipotential curves produced by the points of electrodes in the experiments of Dr. A. Guibhard.

Electric Lighting in Leeds.—It has been decided by the Electric Lighting Committee to place 100 incandescent electric lamps in the mayor's rooms at the Town Hall. The arrangements for an installation to light the Fine Art Gallery, the Victoria Hall, and all other parts of the Town Hall and Municipal Buildings are to be considered by the committee in a short time.

Station Lighting.—Although the rumour current last week that the Citadel Station, Carlisle, was to be lighted by electricity was premature, we may gather from the criticisms that such a course would be welcomed by those who have to use the station. The rumour arose from the secretary having made, unofficially, some inquiries as to the possibilities and cost of such lighting. We have no hesitation in saying that every large railway station in the kingdom should adopt the electric light.

Communication with Lightships.—Replying to representations from the Dover Town Council with reference to communication with lightships, the Board of Trade state that experiments are to be made, over a period of eighteen months, with an electric cable between one of the Goodwin Sands lightships and the shore. If the experiments are found to be successful, cables will be laid between the shore and lightships in dangerous positions.

Cost of Electric Lighting.—M. A. Bayou, former pupil at the Ecole Centrale has recently addressed to the Société Industrielle de l'Est an interesting communication in which he investigates the economical question in twenty-one cases where electric lighting has been substituted for gas in industrial establishments—amongst others the cotton-spinning factory at Blanville-sur-l'Eau. His conclusions are favourable to the establishment of the electric light.

Magnetic Elements. The following are the absolute values of the magnetic elements, as determined, on the first day of the current year, at the observatory of the park of Saint Maur (0° 9' 23" east long.; 48° 48' 34" north lat.):—

Declination	15° 52' 1"
Inclination	65° 14' 7"
Horizontal component	0.19480
Vertical ditto	0.42215
Total intensity.....	0.46520

Metal-faced Wooden Type.—For posters, headings, &c., wooden type is in great favour, by reason mainly of its lightness, but the rapidity with which it becomes affected by wear and tear has hitherto been a great disadvantage. M. L. Duval has recently applied electro-metallurgy to metallising the face of the type, and, according to the *Moniteur Industriel*, has already obtained very favourable results in practice. The *galvanised type* is not only lighter, but is cheaper than metal type, and it is said to be equally durable in certain applications.

Catalogue.—We have received the catalogue of the United Electrical Engineering Company, which contains illustrated descriptions of the apparatus, as well as the prices at which the apparatus can be supplied. We notice one or two new things in this list, such as the steel-yard ammeters and voltmeters of Messrs. Drake and Gorham, p. 40; arc-otter, or small arc lamps, designed for running in parallel circuit with incandescent lamps, p. 36; various designs of pulls and pushes, pp. 76-78. &c. The catalogue extends to nearly one hundred pages.

Reading.—An interesting and able lecture on "Electric Lighting" was delivered last week before the Literary and Scientific Society by Mr. Walter Palmer, B.Sc., F.C.S. The chair was filled by the President, Dr. Hurry, who, in his opening remarks, expressed the pleasure with which the society welcomed lectures on such modern and important discoveries as the applicability of electricity as an illuminating agent. We believe that Mr. Palmer, like Sir D. Salomons, has carefully investigated most of the apparatus employed in electric lighting at his own house.

Bradley's Cell.—This theoretically interesting couple was described by the inventor during the discussion on Mr. Willard E. Case's paper on "Electric Energy from Carbon without Heat." Both the elements are zinc; the negative being in contact with a hot concentrated solution of zinc chloride, and the positive in a cold dilute solution of the same salt. The latter solution is contained in a porous vessel standing in the hot solution, but kept cool and dilute by means of a constant stream of water passing through it.

The positive element, after the couple had been in action, was found to have lost weight, whilst the negative had gained little or nothing in weight. The E.M.F. is 0.3 volt.

The Meriten's Process for Rendering Iron and Steel Inoxidisable.—In this process the articles to be protected from the effects of rust are made the anodes in an electrolytic bath of distilled water at 160deg. or 170deg. Fah.; a plate of copper, iron, or carbon serving as cathode. The surface becomes converted into *magnetite* (Fe_3O_4) by the action of the current; the operation being completed in from one to two hours. If too strong a current be employed, the oxide formed is pulverulent and without adherence. In the case of soft iron, the article, after a first oxidation, must be transferred to the cathode to reduce the oxide formed. After this treatment a very adherent deposit is obtained by a second oxidation.

Physiological.—According to M. Poey, the learned Director of the Havana Meteorological Observatory, there is a very simple means of restoring to life those who have been struck by lightning, or who have accidentally completed the circuit of a high-potential dynamo machine. The means in question is to dash cold water over the whole of the patient's body—for an hour, if necessary until some signs of life are exhibited. M. Poey cites a large number of cases in which people in a condition of asphyxia or "apparent death," consequent upon a discharge of lightning, have thus been recovered. This method of cure—the mention of which is unpleasant in the present weather—is said to have been largely and successfully adopted in the United States.

More Atlantic Cables.—The negotiations of the Dutch Government, says *Industries*, with the Pedro Seduengo-American Telegraph and Cable Company of New York are now so far advanced that it is almost certain that both Dutch Guiana and Curaçao will be in possession of double telegraphic communication with Europe and Holland before the year is out. The above company has an exclusive Brazilian concession for land cables on the coasts of the empire from America. The company proposes to lay cables from Visca, in Brazil, to Paramaribo, the capital of Dutch Guiana, or Surinam, and thence to Willemstad, Curaçao; provided Holland gives an annual subsidy for twenty years. The Dutch Government has agreed to do this. At Curaçao the above cables will connect with others, which the French Compagnie Télégraphique des Antilles is now laying to Hayti and Cuba.

The Electric Light in Italy.—At the great foundry at Terni the electric light has been in operation for about a year. At starting some difficulties were encountered, particularly on account of the vibrations occasioned by the steam hammers. These difficulties were soon overcome, and the lighting is now carried out without interruption. The installation comprises 100 Schward arc lamps, each of 2,000 candles, and over 300 Bernstein incandescence lamps of from 25 to 50 candles, distributed in 12 distinct circuits, which together comprise 10 kilometres of copper overhead wire. Of the above number of arc lamps 43 are employed in the lighting of the workshops, which cover a surface of 26,000 square metres, giving 610 square metres per lamp. The remaining arc lamps are devoted to out-door illuminations over a space of 134,000 square metres, giving 2,400 square metres per lamp. The incandescence lamps are distributed over about 3,350 square metres.

Brussels.—An important change has been made in the organisation of the management of the lighting of the town. M. Aerts, manager of the gas works, having been appointed surveyor of public lighting and gas mains in place of M. Wybauw, who takes charge of the electric lighting, clocks, and telephones. At present the electric light installation of the town only comprises the generating station at the gas works, from which the Theatre de la Monnaie, the Grand Place, and the Theatre du Parc are supplied. It is, however, probable that the municipality will favour a project of erecting an electric light station in the centre of the town, which would serve the principal restaurants, cafés, and some public buildings. Negotiations to this effect have been commenced with the Societe Industrielle of Brussels. The Grand Hotel has already an installation of its own, but there are a number of first-class restaurants in the district around the Grand Place and the Bourse that would undoubtedly be glad of an opportunity to obtain the electric light from such a central station.

New Voltmeter.—Messrs. Siemens and Halske have introduced in their more recent installations of the electric light a new voltmeter, which contains neither springs nor permanent magnets, and is not liable, therefore, to require readjusting when once calibrated. The instrument consists mainly of a large circular coil fixed horizontally, and of a smaller concentric coil, mounted on knife edges, which, in its normal position, is inclined to the former at an angle of about 60deg. These coils are so connected that a current traversing both tends to move the smaller one through the vertical position into the plane of the larger coil; this tendency being counteracted by a small weight. The movable coil carries a light index, which indicates the potential upon a scale on ground glass. The scale being transparent, readings can be taken on either side of the instrument, which is very sensitive. The size is, roughly, 6in. broad by nearly 10in. high. The movable coil is of 800 turns, and has a resistance of 34 ohms. The fixed coil has 1,150 turns and a resistance of 664 ohms. The instrument gives very correct readings from 60 to 110 volts.

Theory of the Telephone.—According to Dr. Rothen, the experiments of Messrs. Shelford Bidwell and Boekmann on the resistance of microphonic contacts lead to the following rules:—1. A multiplicity of contacts is preferable to a single contact in a microphone. 2. The multiple contacts in a microphone should be arranged in multiple arc and not in series. The reason of this is that in the former case the currents are comparatively small; since the total current is subdivided between the different contacts; and that the variations of resistance are relatively greater with weak than with strong currents. 3. The movable carbon should be heavy, in order that it may have a great moment of inertia; but at the same time the pressure should be small; since with a large moment of inertia in the movable carbon the maximum variation of pressure will be obtained, and the variation of resistance will be greater as the initial pressure is smaller. 4. The resistance of the microphonic system should be small, for the lower it is the greater are its variations relatively to the initial resistance. 5. The current traversing the microphonic contact should be as strong as possible under the given conditions.

The Vienna Electrical Laboratory.—The programme of this undertaking has just been issued by the Directors of the Technological Museum, of which the

laboratory forms a recently added section. The work will be superintended by Herr Carl Schlenk, and is to embrace experimental investigations of dynamos as regards output, power consumed, efficiency, and other matters; investigations and reports on executed installations for lighting, power, or chemical purposes, photometry of arc and glow lamps, calibration of measuring instruments, and investigations of primary and secondary batteries. A tariff has been fixed for the work, which will presumably be required very frequently. Thus for testing a dynamo the charge will be from £1. 4s. to £4, according to size of machine: for testing a glow lamp, 16s. to £1. 4s.; arc lamp, £1. 1s. to £1. 12s.; calibration of instruments, 5s. to £1. 12s. Members of the museum obtain a discount of 25 per cent off these charges. Where the work is of special nature, or for outside work, the charge is to be agreed upon beforehand. These fees are levied primarily with the object of covering working expenses. Any surplus is to be equally divided between the exchequer of the museum and the staff of the laboratory.—*Industries.*

Michigan.—Arrangements are now nearly completed for the organisation of a company and the construction and operation of a Van Depoele electric road between Detroit and Mount Clemens, the seat of the famous mineral springs and quite a famous resort for invalids from all parts of the country. Mr. Willie C. Turner, of the Van Depoele Construction Company, is at the bottom of this enterprise. The length of the projected line is 20 miles. It is proposed to locate a central station about midway between the two terminal points, at which the motive power for the entire system will be generated. There will be three electric motors of 50 h.p. each, a 200 h.p. generator with boiler and engines commensurate, and \$20,000 worth of half inch copper wire conductors. It is proposed to have three closed cars, Pullman-built, 30ft. long, and three open cars for summer running, each 40ft. long, with seating capacity for 100 persons. One train will leave Mount Clemens every hour and another Detroit at the same time; and, though stopping at several hamlets *en route*, it is believed that the round trip can be made in two hours. One train will be held in reserve for excursions or emergencies. Light freight, baggage, and mail will be carried in addition to passengers. The estimated cost of the entire line, fully equipped, is \$250,000.

Acheson's Thermo-electric Generator. In this thermo-couple one of the elements is in the form of a tube enclosing the other element; the space between them being occupied either by a fluid in motion or by a substance which, when heated, evolves a gas. The tubular element is heated, and the circuit is completed by bringing into contact with it the coolest portion of the interior element. The fluid in motion may be water; the substance evolving a gas (conductive at a high temperature) may be binoxide of manganese. The idea is ingenious, and the plan suggested certainly allows of a high temperature-difference. No information, however, is given as to the potential-difference obtained; and we think there are two conditions which would be operative in preventing the arrangement from being utilised in practice as a source of electrical supply. One is the comparatively high resistance of the heated fluid or gas, and the other is the alteration of the elements by chemical action. This would probably be greater in the case of the fluid than in the case of the gas; since in the former the passage of electricity can only take place by electrolysis. Still there is here a germ idea that may be developed, and become of

importance in relation to a question—that of cheap electrical supply—which is of interest to all electricians.

New Process of Nickel Plating.—The solution invented by M. M.-J. Arène, the French vice-consul at Mons, is composed of the following ingredients:—

Pure sulphate of nickel	1 kilo.
Neutral ammoniac tartrate	725 grams.
Tannic acid obtained by the ether process	5 "
Water	20 kilos.

The ammoniac tartrate is obtained by saturating with ammonia a solution of tartaric acid. The nickel sulphate should be carefully neutralised. The ingredients are first dissolved in three or four litres of water; the solution is then boiled for about a quarter of an hour, water is added to make up the 20 litres, and the solution is filtered. The bath may be renewed indefinitely by the addition of the same substances in the same proportions. This solution, which is now employed at several of the nickel-plating establishments in Hainaut, allows of the deposition on all metals, by means of a comparatively small voltaic current, of a thick deposit of nickel. The deposit obtained is white, soft, homogeneous and, even when of considerable thickness, free from roughness. No scaling occurs if the objects to be coated have been properly scratch-brushed and cleansed. The cost of nickel deposition with this solution is said to be but little higher than that of electro-coppering.

Self-Luminous Buoy.—Mr. G. M. Hopkins, in the *Scientific American*, says: "Among the tried devices for rendering buoys luminous are lamps arranged to burn for a long time, phosphorescent mixtures, electric illuminators supplied with the current from the shore by means of a cable, and the more recent luminous paint, which absorbs light by day and gives it out at night. Compressed gas has been employed with great success, some of the buoys having been designed to carry six months' supply of gas and to serve as lightships. An apparatus has been designed as an auxiliary to bell buoys and whistling buoys. It is based upon the generation of electricity by the agitation of mercury in a high vacuum or in gas of high tension. The self-exciting Geissler tube involves the same principle. The buoy is adapted to ring a bell by the rolling motion imparted to it by the waves. Advantage is taken of this motion to agitate mercury in annular tubes placed in the upper portion of the frame of the buoy. The tubes are made very heavy and strong, and each contains barriers for causing friction of the mercury against the sides of the tubes. To insure the action of one or more of the tubes at all times, they are inclined at different angles. A slight motion of the buoy causes the mercury to travel circularly in the tubes and generate sufficient electricity to render the tubes luminous."

The Telephone from Paris to Marseilles.—A telephone line is about to be constructed between these two cities. Before deciding upon this undertaking, it was considered necessary to carry out some experiments in long distance telephony, which are of considerable interest, even at the present time. As no single stretch of wire could be found, at least in Europe, extending over 900 or 1,000 kilometers, a line from Antwerp to Brussels was connected with one from Brussels to Paris, this being connected with another line from Paris to Brussels via Mornigies, which, again, was connected with a line from Brussels to Verviers. The total length of line thus included between Antwerp and Verviers was about 1,000 kilometers. Through this distance communications were heard with the

greatest ease. The sound of the voice was clear and distinct, and was heard as well as it is through the present line between Brussels and Paris, on which the results are excellent. The work in connection with the Paris-Marseilles line is to be actively pushed forward; at certain points they have already been commenced. The conductors, of silicated bronze, are to be underground as far as Nogent-sur-Marne, being laid in the Paris and Vincennes drains. From that point they are to be overhead, and will follow the line of the railway. It is hoped that the line will be opened to the public about the month of July next.

Catching a Milk Thief.—The *Boston Herald* tells the following story:—"One of the members of the police force of this city is a thorough electrician, and when off duty is constantly experimenting with captive lightning. He has his residence at the south end wired from attic to cellar, and makes the electric fluid do all that it is capable of therein. For the last few days his milk has been stolen, can and all. He made up his mind that the thief must be captured, and called to his aid his favourite electrical appliances. The milkman had been in the habit of leaving the lacteal fluid on a little shelf beside the rear door of the house. In order to reach this door it was necessary to pass by the front entrance and go down an alleyway some fifty feet long. Mr. Electrician went to work and connected his wires with the shelf, so arranging the circuit that the removal of the can from its receptacle would strike a gong in the dining room. Yesterday morning he went home early and took up his position under the gong. Soon he heard the milkman stop and leave the can in its place. He waited patiently for further developments, and just as he was dropping into a doze, zip! whirr-r! went the gong over his head. To spring from his chair and dart for the front door was but the work of a second, and he landed on the sidewalk at the alleyway entrance in season to nab the marauder, who was coming out with the can in his grasp. He did not take him into custody, but it is fair to assume that there was not dust enough left in the fellow's coat to cause irritation in a midget's optic. The fellow will probably not attempt to purloin that officer's milk for some time to come."

Critical.—The *Journal of Gas Lighting* refers as follows to the data in relation to the economical questions which have been put forward in a pamphlet issued by a certain electric light company:—"As to price, the company profess to charge at the rate of 1s. per Board of Trade standard unit of 1,000 watt-hours, 'which,' they remark, 'is equivalent to a charge of 6s. per 1,000 cubic feet for gas.' Now a nominal 16 candle power incandescent lamp takes a current of 50 watts per hour; and, therefore, at this rate would run 20 hours for a shilling. The same period of supply for a 16-candle gas-burner of the ordinary stamp would require 100 cubic feet of gas, so that the equivalent cost of gas would be 10s., instead of 6s. per 1,000 cubic feet, as stated by the company. Who now is registering 'in favour of the supporters?' It is admitted that if accumulators are employed, the charge for electricity will be 1s. 6d., instead of 1s. per unit, or an advance of 50 per cent. This does not look very promising for the future of accumulators. Seeing what Mr. Offer has to say about the absolute necessity for accumulators, it is rather strange that this company, prepared, as they pretend, to do business on a grand scale, can find it possible to tell their patrons that 'it was once a matter of general opinion, though one from which the experience at Eastbourne and Brighton causes the directors of this com-

pany to dissent, that no electric light distribution scheme is perfect unless it embraces accumulators,' and to declare that these appliances 'add a great item of expense in the production of light, as they only give back in actual working about 70 per cent. of the work put into them, and their first cost and cost of maintenance are both heavy.'"

Miners' Lamps.—We are glad to see that many of the local papers are taking up the question of electric miners' lamps with energy. The *Cardiff Times*, for example, has a long illustrated description of the Swan lamps used in the Rhondda, which commences with the following paragraph:—"The Davy and the Clanny lamps which have, unquestionably, made the names of their inventors famous, are now doomed. The lamp of the future is the electric. It is with great reluctance that many a miner parts with his Clanny. Having worked for twenty or thirty years with it, having entered working places where the atmosphere was foul and returned in safety, being able to detect on the instant, by its means, the slightest accumulation of explosive mixture, he is naturally under the impression that practically no better lamp is required to enable the miner to pursue his arduous and dangerous calling. But even miners' lamps come under the Darwinian theory of the survival of the fittest. A number of electric lamps have for some months past been used at the Ocean Collieries. About 200 are in use at the National Colliery, Cwtych, where the recent terrible explosion occurred, and 600 more have been ordered. Eight hundred similar lamps (Edison and Swan's) have also been ordered by the same proprietors, Messrs. Ward, Watts, and Co., for their colliery at Blaen-Rhondda, and 1,600 more for two collieries in other districts. Few, indeed, were there who anticipated so marvellous a development of this subject when, some four years ago, Mr. David Evans, Bodringallt, manager of the Ferndale and Bodringallt Collieries, had a certain memorable interview with Prof. Abel. It appears that the first miner's electric lamp invented required wires to be carried from the source of electricity along the workings and attached to each lamp. Mr. Evans observed to the professor that such lamps would never come into general use, as the wires would be occasionally broken by falls. 'To render any kind of lamp practicable,' remarked Mr. Evans, 'it must, at all events, be portable.' 'Well,' replied the professor, 'that's impossible. It can never be made.' 'But you see,' said Mr. Evans to me, 'the professor was wrong. We have had portable electric lamps. I believe myself that the electric is the lamp of the future. The Clanny and the Davy have seen their day.' 'Why didn't you go in for electric lamps?' I inquired. 'Well,' replied he, 'We'll wait a bit. We keep watching how things go on.'"

Taunton.—A correspondent to a local paper, discussing electric lighting, says:—"The electric light is so much appreciated in our town that there is little doubt that, notwithstanding the small extra cost, it will before long be extended to the whole borough. There is no disguising the fact that nothing that has been done of late years has so much conduced to the prosperity of Taunton as the introduction of the electric light." Another correspondent writes:—"In your last issue I see there is a letter from a 'Looker On,' in which he quite agrees with me that electrical traction would be an additional attraction to the visitors, but he at the same time seems to be rather doubtful about its usefulness. He then tries to show, by an absurd and at the same time amusing way of arguing, that the Town Commissioners are anybody but the right persons to do their own lighting. He talks in a vague sort of way

about the electrical engineers getting all their experiments carried out at the expense of the well-plucked ratepayer, but, unfortunately, he does not tell us either what these experiments are or where or when they are to be carried out. Does he refer to the testing of the dynamo, or to the testing of the lamps? If so, I may tell him that this is generally done before they leave the electrical works. 'Looker On' cannot have been watching the progress of electrical engineering in general and electric lighting in particular as much as his *nom de plume* would suggest, or else he ought to know that electric lighting has been placed beyond an experimental basis for some time past. It is eight years ago now since the Corporation of Blackpool lighted their esplanade, and at a public meeting last year they expressed themselves satisfied with the results. 'Looker On' should note that the Blackpool Corporation supply the electricity from their own plant. There are at the present time 236 companies, and over 25,165 are lamps in use, in the United States, lighted by one system alone. As regards electrical traction, there are nine electrical tramways in Europe which have been working for more than three years, and there are thirteen working in America, besides many more which are in course of construction; and it is a means of traction which has been proved many times to be cheaper than horse traction. It would appear to me that since the private companies have to make a profit on the lighting of the town, the town commissioners could do the lighting of the town cheaper by having their own plant. It is evident that the shrewd Yorkshire folk, as represented by Bradford, take this view."

The Treatment of Antimony Ores by Electrolysis.—It has been proposed to apply on a large scale for the extraction of antimony from its ores, the process of analysis suggested by Classen, and based upon the separation of antimony dissolved in a solution containing sodium sulphide. Any compound of antimony capable of dissolving in such a solution may be employed; but it is important that there should not be a preponderance of either sodium or sulphur in the material to be treated, for an excess of the former increases the electrical resistance, whilst an excess of the latter produces a precipitation of sulphur. The mixture corresponding to the formula

would be that best adapted for treatment were it not for its instability; it may be approximated to by employing a high proportion of sodium. The sulphide ores of antimony, containing Sb_2S_3 , are well adapted for electrolytic treatment, even when they are poor, since the metallic compound readily dissolves in the sodium sulphide solution even when very dilute. After the solution has been brought to 12deg Baumé, about 3 per cent. of its weight of sodic chloride is added to it in order to increase its electrical conductivity, and it is run into iron tanks which may be employed as cathodes. The anodes are of lead, and the E.M.F. of the current is from 2 to 2.5 volts per tank. The antimony becomes deposited either in powder or in brilliant scales. After it has been collected, it is washed in the first place with water, to which a little sodium-sulphide or hydrate, or ammonia, has been added, then with pure water, next with water slightly acidulated with hydrochloric acid, and lastly with pure water, after which it is dried and melted. In a first experiment, with 9.62 kilos. of sulphantimoniate of sodium and 8 kilos. of sodic-hydrate, 2.437 kilos. of antimony were obtained out of a total

quantity of 2.440 kilos. The mother liquor contained 2.4 kilos. of sulphhydrate of sodium (NaHS), 1.2 kilos. of sulphide of sodium (Na_2S_2), and 1.5 kilos. of thiosulphate of sodium ($\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$). In another trial, with 3.4 kilos. of antimony sulphide and 7.2 kilos. of sodium sulphide, the loss was 5 grams on 2.4 kilos. of antimony; the mother liquor in this case contained 1.3 kilo. of sulphhydrate, 1.2 kilo. of sulphide, and 1.6 kilo. of thiosulphate of sodium. The reactions occurring respectively at the anode and at the cathode are indicated by the following equations:

The Impending Cable Compromise.—The *Financial News* says:—"The public have become so familiar with a state of war among the cable companies that it seems to be difficult for them to realise the possibility of its coming to an end. But, as we explained on Saturday, it has for several months been evident to the initiated that an early compromise was inevitable. The information we have published from New York came to us from a very reliable source, and we have no doubt that its accuracy will be demonstrated within a very short time. It is probable, indeed, that the chairman of the Anglo-American Telegraph Company may have some communication to make on the subject at the approaching half-yearly meeting of shareholders. Meanwhile, we are assured that the negotiations, if not actually completed, are on the eve of completion. The point which it has been found most difficult to agree about is the new rate, certain members of the pool being in favour of 1s. 3d. or 1s. 8d. per word, while others are for the plain and simple shilling. In August last a correspondent of the *Statist*, in advocating mutual concessions between the cable companies, made a very striking exhibit of the good effects which even a moderate advance of tariff would produce. He showed that a 1s. 3d. rate would pay 4 per cent. on Ordinary, 6 per cent. on Preference, and 2 per cent. on Deferred, while a 1s. 8d. rate would yield 6 per cent. all round. The following were his calculations:—

Per Last Half-yearly Report.

Gross receipts of 8d. per word.....	£94,000
General working expenses	39,000
Surplus	55,000
If rate 1s. 8d. is proposed, result would be gross	£13,000
Deduct for loss wires consequent on higher rates, say 25 per cent.....	78,250
Working expenses	234,750
Half-year's interest on reserve £1,000,000.....	39,000
Dividend at 6 per cent. for six months on £7,000,000	195,750
If rate 1s. 3d. per word, result, say	213,250
Deduct for loss wires consequent on higher rate, say 20 per cent	17,000
Interest on reserve	210,000
Dividend at 6 per cent. for six months on £7,000,000	235,000
Deduct for loss wires consequent on higher rate, say 20 per cent	47,000
Interest on reserve	188,000
Working expenses	17,500
Dividend at 4 per cent. on Ordinary, 6 per cent. on Preference, and 2 per cent. on Deferred for half-year	205,500
	39,000
	166,500
	£140,000

CONSTANT PRESSURE IN ELECTRIC TOWN MAINS.

I.

The first condition in any system of public supply of electricity is that the lamps or motors installed should be perfectly independent of each other. The householder naturally demands that he should be able to switch on one or more lamps at any hour of the day or night, and that whatever may be the number of lamps in use in his own or other houses each individual lamp should always give the same amount of light. The simplest plan to make the lamps independent of each other is to put them in parallel circuit; but then the difficulty arises that those lamps which are farthest from the centre of supply must at those times when a large amount of current is consumed give a somewhat less brilliant light than is the case when only little current is consumed throughout the district. To obtain absolute constancy of light is a physical impossibility, for this would require mains of no resistance, but we can, with a judicious arrangement of conductors, reduce the variations of pressure within such limits that the light of each lamp may be considered as sufficiently constant for all practical purposes. That a certain variation of pressure is unavoidable, has been recognised even in the early days of electric lighting when speculators and company mongers pretended to be in a position to entirely supplant gas by some special system of electric lighting, and a certain limit of variation in the pressure has been fixed by the Board of Trade rules. The limit, it is needless to say, was not fixed arbitrarily, but on the recommendation of scientific witnesses called before a Parliamentary Committee, and in this as in many other things the witnesses were wrong. To allow, as the Board of Trade rules did, the pressure to rise 5 per cent. above and to fall 5 per cent. below the standard would be absolutely fatal to the electric light, for no householder would submit to the corresponding variation in the amount of light supplied. It must be remembered that the light intensity of a glow lamp does not vary directly as the potential difference at the terminals, but in a much greater ratio. If the resistance of the carbon filament were independent of the current the energy consumed in the lamp would vary as the square of the pressure and the light emitted would vary in a slightly higher ratio. But the resistance of the filament is not a constant. It becomes lower as the current increases, and, therefore, the variation of light is considerably greater than the ratio of the square of the minimum and maximum pressure. The exact relation between pressure and light is a very complicated one, and is different with different lamps, but for comparatively narrow limits on either side of the standard pressure we may reckon that the light varies as the pressure to the power 2.5. Thus if 100 volts be the standard pressure and 105 the maximum, according to the original Board of Trade rule, the light would increase by about 13 per cent., whilst a drop in pressure of 5 volts would diminish the light by about 14½ per cent. Were such a variation of pressure allowed a 16 candle lamp would occasionally give a light of 18.1 candles, and at other times of only 13.7 candles, a variation quite inadmissible, to say nothing of the further drawback of variations in the colour of the light. This would be either brilliant white or reddish yellow according as the pressure is a maximum or a minimum. The limit of 5 volts out of 100 up and down is, therefore, by far too wide, and to obtain a really serviceable supply we would have to arrange our mains so that the pressure could never exceed, say, 1½ volts above, or fall more than 1½ volts short of the 100 volt standard. Under these circumstances the light of a 16-candle lamp would vary between 16.58 and 15.36 candles, a variation probably smaller than that continually taking place in our gaslights where a very sensitive regulator is not employed to keep the gas pressure constant.

Having thus fixed the limits within which the potential difference may rise and fall, as the demand for current varies in different points of the district and at different times, the question arises as to the best way of laying down the mains so that these limits should not be exceeded. There is, however, also another consideration, which must influence the calculation for the size of mains, viz., that of economy.

Every conductor from the single lamp wire to the heaviest underground cable must waste a certain amount of energy by the resistance it opposes to the passage of the current. This energy must be supplied by the dynamos at the central station in addition to that consumed by the lamps, and has ultimately to be paid for in the shape of an increased coal bill. Now to keep down the energy thus wasted and the corresponding cost of fuel, water, oil, &c., we should employ conductors of very low resistance—that is to say, of large cross section, but in doing so we increase the annual charges on the system in another way. To draw up a proper balance sheet of the cost of supplying electricity from a central station we must obviously include the item of interest on the capital outlay and the depreciation of plant. The revenue derived from the sale of current to the subscribers must cover these items, the working expenses, and should leave a balance by way of profit on the undertaking, and in some cases also provide for a sinking fund. By employing lighter mains we diminish the items of interest, sinking fund, and depreciation, but we increase that of working expenses, and to a certain extent also that of capital outlay on the generating plant at the central station, since owing to the greater waste of energy in the mains, more steam and dynamo power is required. On the other hand, if we wish to economise power, both in the first outlay for boilers, engines, and dynamos, and in the annual working expenses, we must take care to waste as little as possible in the mains—that is to say, we must make them very heavy. But in taking this course we burden the installation with a heavy charge for interest on the value of copper put into the ground. By going to extremes in this direction, it is quite possible that, after paying off interest, no profit is left; whilst if we go to extremes in the other direction by stinting the mains, it may happen that the working expenses and interest on the plant at the station will absorb all the revenue, and again no profit will be left. It is evident that between these two extremes there must be one particular size for each main, which, taking all things into consideration, is most economical—that is to say, will leave the largest margin of profit out of a given revenue. Sir William Thomson has proved that for a single pair of mains, having to carry a constant current, the most economical section is that for which the interest and depreciation equals the annual cost of the power wasted; but when we have to deal with a complicated network of mains, where the current is by no means constant, and where the maximum current only flows for a few hours per day, as must necessarily be the case in a system of general supply, the calculation of the most economical section of conductor becomes extremely complicated. If it were only a question of current variation in a single pair of conductors we could deal with it in a fairly satisfactory manner as has been shown by Prof. Forbes in his earlier lectures before the Society of Arts. For instance, if the full current only flows for four hours per day, and if during the rest of the time the demand varies to $\frac{3}{4}$, $\frac{1}{2}$, $\frac{1}{4}$ current, and no current at all, the most economical section of conductor will be about one half that which would be required were the full current always flowing, the exact ratio being determined by the proportion between the different currents flowing at every hour of the day. But in practice we are seldom in a position to predetermine with anything like accuracy the shifting and changing of the demand for current throughout a district, and therefore only an approximate solution of the problem is possible. Reduced to its simplest form, the problem is to determine what pressure should be lost in the mains when the full supply is on, to insure, all things considered, a maximum of profit on the invested capital. We do not propose to further discuss this question at the present time, but may mention that in a number of central stations, with which we are acquainted, the loss on a 100 or 110 volt service varies at full supply between 10 and about 25 volts, and as these stations are paying concerns, we may take it that a loss of about 20 volts on a 100 volt distribution will, under ordinary circumstances, be the most economical.

In the beginning of this article we have said that subscribers would not tolerate a larger variation than about 1½ volts up and down from the 100-volt standard, and our readers will probably ask how we can reconcile with this

statement the result now arrived at, according to which the loss of pressure should be as much as 20 volts. The conclusion is, however, only apparent and not real; for the small loss refers to those mains only to which the house services are directly connected, whilst the large loss refers to mains which are not tapped by house wires at all, and only serve to feed the distributing network of mains at certain points. In laying down these feeders we are untrammelled by the condition of constancy of pressure along the whole of their length, and can therefore determine the size strictly in accordance with economic principles, whereas in the network the question of the most economical section must be set aside for that of constancy of pressure, without which householders would refuse to have the electric light at any price. Thus, we see that the distributing plant is naturally divided into two portions—one in which constancy of pressure is the first and absolutely essential condition, and the other in which a large variation of pressure may take place, provided economy in working is assured. The former we call the network and the latter the feeders. To make the distinction between the two clear, we shall assume, by way of illustration, that we have to light a straight street 400 yards long, the central station being at one end. Let there be three lights per yard of frontage on each side of the street, or 2,400 lights fixed. Of this number probably only one-half will be simultaneously alight, so that the station even in the busiest hours of the evening will have to send out current for the supply of only 1,200 lamps. At 60 watts per lamp and 100 volts pressure a current of 720 amperes would therefore be required. If the station be connected directly with the main—that is, without the intervention of feeders tapping the main at different points, the whole current enters at the station end, but as current is taken off at every house the current flowing in the main will gradually diminish towards the far end. If the current taken off per yard run is constant throughout the length of the street, the difference of pressure between the ends is, according to a well known law, approximately half that which would obtain if the whole current were taken off at the far end. Now, at the full supply, the difference of pressure will be a maximum, and in the day time, when very few lamps are alight, it will be nearly zero. If the lamps were all standardised to exactly 100 volts, then 101·5 and 98·5 volts would be the highest and lowest limits of pressure on any point of the main. In other words, the total loss of pressure at full supply must not exceed 3 volts. In this case the pressure at the station would have to be 101·5 volts for full supply, and anything between 100 and 98·5 volts at minimum supply. This margin of 3 volts is very small, and would require an almost prohibitive amount of copper in the main. Let us, then, see how we can increase the margin and reduce the weight of copper. One method which immediately suggests itself is to employ lamps of slightly different voltage. Say we take lamps graded into half volts from 101·5 down to 98·5 and fix them according to their voltage, those of 101·5 volts nearest the station, those of 101 volts a little further on, those of 100·5 volts still further, and so on, till we come to the lowest volt lamps, which would be fixed at the end of the main. We can now keep the pressure at the station at 103 volts for the full supply, and allow a loss of 6 volts in the main. The nearest lamps would be overstrained by $1\frac{1}{2}$ volts, and the farthest lamps would get $1\frac{1}{2}$ volts too little pressure when the full supply is on; whilst when running light we would keep 100 volts at the station and overstrain the farthest lamps by nearly $1\frac{1}{2}$ volts, the nearest lamps getting $1\frac{1}{2}$ volts too little pressure. This, then, is the best we can do under the given condition. The resistance of the main must be such that when the whole current is sent round it, that is 100 yards out and 100 yards home without intermediate cross connections, a pressure equal to twice the permissible loss (or, say 12 volts) is required. The resistance of 800 yards of single main must therefore be

$$\frac{12}{720} = \cdot 0167,$$

or 0·0208 ohms per 100 yards. With copper of 98 per cent. conductivity a sectional area of 1·19 square inch would be required, and the weight of copper in the main would be about 4·5 tons, being at the rate of $1\frac{1}{2}$ lb. per lamp fixed.

Now, if it had been possible to place the station into the

centre of the street, the distance of the farthest lamp would be half that of the previous case, and only half the current would be sent into each of the mains on either side of the station. This would at once enable us to reduce the cross section of the conductor to one-quarter of its previous dimension, and the weight of copper in the mains would come out at only a little over 1 lb. per lamp fixed. But since we cannot shift the station from the end of the street to the middle we must do the next best thing, viz., lay a separate feeder from the station to the centre of the street, and disconnect the main from the dynamo at the station. For the 200 yards of main which lie between the station and the feeding centre, the current will then have to traverse a greater length of conductors than before (running out on the feeder and back on the main), and it might appear as if on this account the arrangement must be bad. But in reality this is not so, for the loss of pressure on the feeder may be anything we choose to make it without in the slightest degree interfering with the constancy of pressure on the main. Thus, if we assume that with full work the feeder may lose 20 volts, its resistance in the 200 yards out and 200 yards home would have to be

$$\frac{20}{720} = \cdot 02775, \text{ or } \cdot 00693 \text{ ohms per 100 yards. Its area}$$

would be 36 square inch, and the total weight of copper in the feeder would be about 14 cwt., or at the rate of 69 lb. of copper per lamp fixed, which added to the weight of copper in the main, brings the total up to 182 lb. per lamp fixed. Thus we see that, whereas 4½ lb. of copper were required per lamp when the end of the main was directly connected to the station, only a little over 1½ lb. is required where the connection is by means of a feeder to the centre of the main. Now, if one feeder produces such a saving it is reasonable to suppose two feeders will still further economise copper. Let us see. Suppose we lay one feeder to a point on the main 100 yards from the station and the other to a point 300 yards from the station, and consequently 100 yards from the far end. Each feeder will now supply 200 yards of main, and carry a current of 360 amperes when the full supply is on. We have now again halved the current in the main and halved the distance of the farthest lamp; consequently, with the given loss of 6 volts, we can employ a main of only one quarter the cross section. The weight of copper in the main will therefore now only be 28½ lb. per lamp fixed. If a pressure of 20 volts is to be lost in the feeders, we find that the longer of the two must contain 1,860 lb. of copper and the shorter 210 lb., making in all for the feeders 2070 lb., or 865 lb. of copper per lamp fixed. The total weight of copper in the distributing plant comes therefore to 1·15 lb. per lamp fixed. Taking as our standard of comparison the weight of copper required in the case where the main is directly connected to the station, we thus find that we require

With one feeder . . . 40·5 per cent. of this quantity of copper.
With two feeders. . . 25·6 " " "

The advantage of the feeder system is thus made apparent at a glance, but in order that the distribution may be equally perfect in the case where we supply not only a single main, but a complicated network of mains by means of feeders, it is necessary that the pressure at the feeding centres should be perfectly under the control of the engineer at the station, and we shall deal with this part of the subject in our next issue.

ELEMENTARY TESTING SUITABLE FOR ELECTRIC LIGHTING SYSTEMS.

BY THOMAS GRAY B.Sc., F.R.S.E.

[All rights reserved.]

The object of this series of articles on "elementary testing" is to describe in as simple a manner as possible the methods of making, and the instruments used for, the tests which are usually required by those engaged in making installations of electric light or of electric power. Electrical testing, as the making of a certain class of electrical measurements is often called, has generally been treated

with a view to its applications in telegraphy, and, indeed, the whole subject has been developed because systematic testing is essential to the telegraph engineer. Since the application of electricity to the production of light and of power, has become an important branch of industry, many measurements which were not required in the telegraphic application have become essential. There are, of course, a great many of the measurements in common use by the telegraph engineer which are necessary for safe and successful practice in electric lighting, and thus to a large extent the tests given in these articles will be the same as those given in standard works on "telegraph testing." This applies particularly to the part of our subject which is to come first—namely, the tests required during the wiring of an installation; the tests for the quality of conductors and insulators; the measurement of the resistances of the coils of different parts of dynamos, motors, transformers, &c.; the tests for the degree of perfection of the insulation of the different turns of the coils from each other, and of the whole from the bobbin in which it is wound, and so on.

The methods of making the different tests will be described and illustrated, where necessary, by simple diagrams, any peculiarity in the apparatus required being, if necessary, referred to at the same time. The detailed descriptions of the various forms of instruments that seem most suitable for the purpose will, however, be given in a collected form after the more elementary part of the subject has been treated. The tests given in the present article are for the most part of a purely qualitative character. They are convenient sometimes, as they show whether there is any bad fault, but it must be clearly understood that they should only be used *during* construction or preliminary to a more systematic series of measurements.

FIG. 1.

Consider first an installation wired, let us suppose, for incandescent lighting on the parallel or multiple arc system. Such a system consists essentially of two leads run parallel to each other throughout the whole installation. In actual practice it consists of one or more pairs of main leads, from which pairs of branch leads are run to the different parts of the system. These branch leads, or systems of leads, are usually connected to the mains through switches and fuses, and so also in some cases are the sub-branches connected to them. This gives rise to a more or less complex system of connection, and hence to considerable chances of accidental breaks and other faults in the circuit. That all the connections have been made up to any point in the system may be quickly tested as follows: First, test whether the two main leads, each with its system of branches, is insulated from earth. Second, test whether the two mains and their branches are insulated from each other. Third, test, by putting a bridge across the mains or pair of branch mains, whether there is a circuit. These three tests, the third being applied to all the systems of branches, are sufficient to show whether the connections are complete all through the installation up to any point in its progress. They may be made in the following manner:

1. *Insulation of main leads.*—Connect, as shown in the diagram, Fig. 1, one pole of any convenient battery, B, of one or more cells to one of the terminals of a galvanometer or "detector," G, and the other pole to earth, say through a water pipe or a metal plate, E, in contact with damp earth. Observe whether any deflection is produced on the galvanometer, G, when it is put in contact with the mains M or M₁. If the work has been systematically carried through, this test will almost to a certainty give a negative result. It is of great importance, especially in large installations containing a multiplicity of branches, that the insulation of the leads from earth and from each other should be regularly tested as the work progresses, because a breakdown of insulation is somewhat

troublesome to localise. Assuming for the present that the insulation is found to be perfect, we come to—

2. *Insulation from lead to lead.*—Referring to Fig 1, disconnect the battery from earth and connect it to one of the mains M or M₁, and observe whether *no* deflection is produced when the free electrode of the galvanometer is connected to the other main. Having made sure by this test that the whole system of leads is, so far as this rough test will show, properly insulated, we come to test 3.

3. *Continuity.* Connect in succession the ends of the branch leads and observe whether in all cases a *strong* current flows through the galvanometer. This completes the three tests. In the event of a defect being found by any of the three tests, it will generally be possible to find it by simple inspection without having recourse to electrical methods. Methods of localising faults will, however, be given further on in connection with quantitative measurement.

The galvanometer used in these tests need not be of fine construction, but it is convenient to have it roughly graduated and its resistance known, so that its indications give a rough idea of the resistance in the circuit. The resistance of the galvanometer should be moderately high—say, 1,000 ohms, or more—in order that it will give a sensible deflection, even when the insulation is considerable, and should be provided with a controlling magnet powerful enough to bring the deflection within the range of the scale when the battery is short circuited through it. It is of great importance that both the galvanometer and the battery should be portable, and little likely to get out of order. In order to

FIG. 2.

make the test roughly quantitative the deflection produced when the two poles of the battery are connected direct to the terminals of the galvanometer should be noted at the beginning of the test, and the deflections, if any, when the insulation tests are being made. Suppose the current produced by the battery joined direct to the galvanometer gives a deflection d , and the leakage current through the insulation gives a deflection d_1 . Then, if the graduation is such that the deflections are approximately proportional to the current, and the resistance of the instrument and battery together (practically that of the instrument alone) be called R , we get for the insulation I ,

$$I = R \frac{d}{d_1} \text{ approximately.}$$

When an instrument having a resistance as high as is here recommended is used for the third, or continuity test, the deflection should not be appreciably diminished by the introduction of the resistance of the leads, as they would in almost any electric light installation have a resistance only equal to a small fraction of the resistance of the galvanometer. At first sight it would appear that by using a low resistance galvanometer and battery, the method just given of getting an approximation to the insulation of the leads would also serve to indicate whether the resistance of the leads is nearly right, and hence would serve to detect bad contacts due to careless workmanship, bad keys, or bad fuses. The method is not nearly so satisfactory when applied for this purpose, because it is not as a rule convenient to keep a battery of sufficiently low and constant resistance at hand. It entails besides, the use of two galvanometers or of one with both a high and a low resistance coil. The following method of obtaining the required information with the high resistance instrument is much more satisfactory.

Referring to Fig. 2, let M and M₁ be the main leads as before, and let m_1 and m_2 be a pair of branch leads connected

at their ends by a thick wire g . Let the ends of M and M_1 be connected through a resistance r and a battery B , so that a continuous current will flow through the circuit. Join the galvanometer across from a to c , and read the deflection; then move the electrode on c to the end of the resistance at b , and again read the deflection. Let the deflection be d and d_1 , as before, and let x be the sum of the resistances of the main and branch leads, and we have approximately, when the resistance of G is great compared with that of the leads or of r ,

$$x = r \frac{d}{d_1}$$

That this equation is true will be readily seen when the following considerations are kept in mind. The same current is flowing through r as is flowing through the leads, and hence the E.M.F. required to send the current through the resistance and through the leads are as r is to x . The deflections of the galvanometer are as the E.M.F.'s on its terminals, or $\frac{d}{d_1} = \frac{x}{r}$, which is the equation given above.

The presence or absence of bad contacts in the circuit can readily be inferred from the value of x and the known length and resistance of the leading wires. Should the test indicate a faulty place, it may be found by applying the terminals of the galvanometer to the two sides of the joints, switches, &c., in succession, until the faulty one is found. The method of measuring resistances here indicated was given by Sir William Thomson, and is commonly known as Thomson's potential method. We shall have several examples of its usefulness in the course of these articles. The galvanometer is used to measure the difference of potential between the ends of the resistances, and hence must have sufficient resistance to prevent its application from sensibly altering that difference of potential.

The three tests here given are generally sufficient to insure good workmanship so far as the wiring of the installation is concerned, and if they are properly attended to there is very little chance that the final tests will show any serious flaw. A similar series of tests should be applied after the lamp holders, switches, fuses, &c., have been tested. This is of great importance in all cases, but especially so when the electric light fittings are fixed to gasaliers and gas brackets, as is not unfrequently done. The insulator test shows whether all the wires and fittings are properly insulated from the gas-pipes, and the test of the insulator from lead to lead insures that none of the lampholders are short-circuiting the leads. The third test should then be repeated by the method illustrated in Fig. 2, each of the lampholders being short-circuited in succession, so as to insure that the lamp branches have been properly soldered on. This last may seem an unnecessary amount of trouble, but experience shows that faulty connection is not uncommon, especially where the leads are covered and the workmen have the opportunity of simply twisting one wire round the other, and then covering it up from view. It is well that the workmen should understand that bad connections are likely to be discovered, although they may be hid from view. There can hardly be anything more dangerous than bad joints in electric light wires, covered as they often are by inflammable material. The joint heats or, if there is any shaking sparks, and fires are the consequence.

It is convenient to repeat test 3, after all the lamps are hung in position and the keys of them all closed, so as to obtain an approximate idea of the value of the resistance of the lamp circuit for future reference. This is of most use in large factory installations where a considerable number of lamps are turned on by one switch, which entails the trouble of removing all the lamps before a test of the leads can be made. More exact methods of testing working circuits will be given further on, but a test such as here indicated, when made even with comparatively rough apparatus, will often serve the purpose. The insulation of the whole system from earth can of course always be tested, even when the lamps are in position, both leads being taken together. When, however, an earthed return is used, or when, as is sometimes practiced in ship lighting, the ship is used as a return, the insulation test cannot be applied to the whole insulated lead unless the whole of the

lamps are either removed or cut out by switches. The insulation test then becomes identical with the test of the insulation between the leads.

(To be continued.)

ELECTRIC LIGHTING OF THE TOWN OF EMS.

Since last spring Ems has had a central electrical station, established by the Spieker Co., which, from certain points of view, is of special interest. From the commencement the installation has worked uninterruptedly, and in a very satisfactory manner.

The two steam-engines employed are high pressure, and each of 70 h.p.; they are used for driving the dynamo only after dark, being utilised in the daytime in pumping water. Three shunt-wound machines are used, each producing, at 600 revolutions per minute, a potential difference of 230 volts, with a current of 80 amperes. The velocity is maintained sensibly constant by the steam-engine regulators. The three machines can be worked together, connected in parallel, and supply a number of different circuits. The loss of potential is about 15 per cent., i.e., 30 volts. If a single circuit were employed, therefore, the lamps nearest the machines would be worked under an E.M.F. higher by this amount than that of the most distant lamps. The use of lamps varying from 250 to 200 volts

would not meet the difficulty; for the loss of potential would diminish with the number of lamps in circuit. These considerations led the company to adopt seven circuits, each of different length and section. Each circuit itself comprises arc and incandescence lamps, varying in luminous power and in number; their total number is about 885, distributed amongst 40 subscribers. The 10 and 16-candle lamps require a difference of potential of 100 volts, and are arranged two in series. The 30 candle lamps are mounted with two filaments, which together take 200 volts. The conductors are supported by porcelain insulators on posts.

But the interesting feature of the installation is the automatic regulator attached to each circuit, and maintaining a potential difference of 200 volts, whatever may be the external resistance. This apparatus is represented in the above diagram.

Wires from the leads are connected to the relay R , the armature of which, for a normal difference of potential, is held between the two contact-pieces a and a_1 . When the potential augments, the magnet attracts the armature, making contact with a_1 ; when, on the other hand, the potential diminishes, a spring overpowers the magnet, making contact with a . When, therefore, there is a variation from the normal, a current traverses one of the electromagnets, E and E_1 . The plate of iron, P , attached to a rack in connection with the rod z , is thus brought into contact with one of the two pulleys, S and S_1 , which revolve in opposite directions. The rod z is thus made to revolve

and to alter the position of the sliding contact, c , introducing more or less resistance in the main circuit until the normal potential difference is restored, the movement of c being limited by the stops, l and l_1 . When c reaches either of these, the current is broken at K or K_1 .

The electric light is in operation at Fms only during the season—from May to September inclusive.

COX-WALKER'S TELEMETER.

It will be remembered that at the last British Association meeting Mr. Upton read a paper describing Clark's tele-

meter, connected respectively with the Zn and Cu of a divided battery, the centre of which is permanently to earth, the levers themselves being connected to line by the terminals as shown (the bottom springs are merely used to steady and check the back swing of the weighted arms).

On the driving wheel being revolved from left to right, it will be seen that the left-hand lever is raised by the pins in the wheel, and, as soon as freed, the weight causes it to swing into contact with the spring immediately above it, and thus send a negative current over the line to the indicator. When the pinned wheel revolves in the opposite direction the right hand lever acts similarly, and sends a positive current to line.

FIG. 1.

meter. Instruments of this kind for indicating the height of water have been used for some years. At the late Newcastle Exhibition Messrs. Cox-Walker exhibited an apparatus which is herewith illustrated, and which is speci-

The line wire is connected to one of the terminals, L, on the indicator (Fig. 2) and earth to the other terminal E. The current from the contact apparatus always passes through both coils. The pivoted cores carrying the driving

FIG. 2.

ally suited to indicate the varying height of water in a reservoir, or wherever required.

Fig. 1 shows a central grooved wheel, around which is passed the cord or chain to which the counterweighted float is attached; or, if necessary, a larger grooved wheel may be fixed outside of this apparatus, but connected to it by the universal joint shown in the illustration. Contact levers with spring catches and weighted arms swing on centres as shown. Above these arms are adjustable contact

anchors, BB, are polarised by means of permanent magnets fixed in the base, and either one or the other is moved in accordance with the nature of the current received.

The driving anchors act separately upon the teeth of the wheels, the anchors and cores being kept permanently in position by means of spiral springs. Bevel gearing, with a crown wheel fixed on the spindle, gives the motion to the index pointer of the dial, indicating a rise or fall in the river, harbour, or tank in which the float may be placed.

Fig. 3 shows the usual method adopted for calling attention to the state of affairs by means of a bell.

It will be seen from these illustrations that Messrs. Cox-

were free poles. As a fact, when there is an equality of energy in the two coils bb' and cc' , the poles S and S' , having equal values, are situated equidistant from the point

FIG. 3.

Walker have designed a very effective piece of apparatus, and one that should come largely into use.

MAQUAIRE'S ELECTRO-DYNAMIC BALANCE OR REGULATOR.

In a patent recently issued to M. Maquaire, in France, there is described a system of maintaining a constant current or constant resistance by means of a movement or by means of an equilibrium arrangement. For this purpose the inventor has adapted an arrangement in which the regulating forces employed are exclusively electrical, and which is composed of two distinct parts, viz.:

1. A sensitive electric motor of which the speed and the direction of rotation are subjected to electric forces solely; and
2. An arrangement for transmission having little passive resistance, and which spreads the work over a long period of time in order to reduce as much as possible the work of the motor during a unit of time.

FIG. 1.-

The electric motor which is brought into requisition here is that of Thiholeff, which, with some changes, is shown in the accompanying illustration, Fig. 1. A is a Pacinotti ring, NS being the polar line, in which the magnetic core may be made of a single piece or of several. Over the winding the armature is covered with an envelope of iron in communication with the magnetic core, which thus gives a more regular and continuous field between the pole pieces and the armature.

As will be seen in the case of the arc regulator, the coils bb' are placed in shunt to the arc a , and the coils cc' are energised by the main current, the armature winding being either in series or in shunt circuit. If the free poles are N' and N'' , there are formed two south poles at S and S' , but in this particular case these two latter poles, instead of neutralising each other, act on the ring as if they

were free poles. When, on the contrary, the conditions of normal regulation are modified, and the energy, for example, is greater in bb' than cc' , S' increases in strength and approaches nearer to S . From this there results a disturbance of the equilibrium of the pole N and the armature A , which tends to turn in that direction; while, on the other hand, it is attracted in the same direction by the preponderance due to the same cause of the pole N' over the pole N'' .

The arrangement shown in Fig. 2 shows the application of the arrangement to a regulator for governing the current from a battery. The current passes into shunt coils cc' , and into the armature by the brushes d and d' , and from there

FIG. 2.

to the sleeve E in contact with the spindle GG' . The latter is set in motion by the endless screw F , which is carried by the shaft extended from the armature and which gears with the worm wheel G'' . During the movement or rotation of the spindle GG' , a helicoidal sheet of metal g touches successively the contacts of a series of resistances r shunted around the line current; finally, at the two points of the distributor the current is taken off, which energises the coils bb' of the regulator. It will be seen that the electro-dynamic balance is set in motion in one direction or another by the addition or withdrawal of resistance until the strength of the current has obtained a normal value by which the regulator is brought to a standstill. It will be seen that, as shown in Fig. 1, the regulator is designed, among other things, to be used as the regulating mechanism of an arc lamp.

THE ELECTRICAL ENGINEER.

Price Threepence; Post Free, Threepence Halfpenny.

Editorial and Publishing Offices:

139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. Special Terms for a series can be arranged on application.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at **THREE WORDS for ONE PENNY**, with a **MINIMUM** charge of **SIXPENCE**.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsgent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months.	6 months.	12 months.
United Kingdom..	3s. 3d.	6s. 6d.	13s. 0d.
Within the Postal Union	4s. 4d.	8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 we gave a Portrait of E. GRAVES, Esq., President of the Society of Telegraph Engineers, and stated our intention of giving a series of Portraits of eminent Electricians of the century. In fulfilment of our promise we issue with this number a Portrait of W. H. WOLLASTON, M.D., F.R.S., who was in his scientific prime at the beginning of the century. This will be followed by SIR HUMPHREY DAVY, F.R.S., whose fame as an electrician is still more prominent than that of WOLLASTON. Portraits of Past Presidents of the Society are in preparation, and we hope soon to have ready that of PROF. D. E. HUGHES, F.R.S.

THE GOVERNMENT AND TELEPHONY.

It needs but a feather to show which way the wind blows, or a sentence to show the direction of the thoughts of the Post Office officials in all that concerns telephony. The reply of the Postmaster-General to the influential deputation that waited on him at Oxley Manor, near Wolverhampton, on Friday last, will afford much room for thought to all interested in telephony. The deputation sought Mr. Raikes to complain of the anomalies to be found in the postal and telegraphic regulations. Among other things the deputation state that the charge for sending telegrams from post offices through the telephone to their destination was too high. Mr. Raikes in his reply, said, "With respect to the telephone, he agreed that the position of telephoning was unsatisfactory, and was due to various causes. He thought one of the principal causes was the generosity of his predecessor, the late Mr. Fawcett, whose statements had been interpreted in the direction of non-interference with the rights claimed on behalf of the telephone companies. He thought that before long steps must be taken to place telephony on the same footing as telegraphy, under the control of the Government or entirely with private enterprise. He did not think the present system could be justified." We have taken *The Times* report of the deputation, the whole of which will be found in another column, and all that relates to telephony merits instant attention. It is quite clear from what Mr. Raikes said, as well as from what he left unsaid, that practically a determination has been come to to deal with the whole question of telephony. The subject presents two views—the one from a departmental or, better, a public standpoint, the other as it affects shareholders. The ultimate result it is not difficult to foresee. The telephonic as well as the telegraphic service will come wholly under the control of the Government, for under the circumstances no other course is open. The telegraphic service of the country has been acquired at great cost, the returns show that the initial expenditure was too high, and an annual loss is incurred. Telephony, especially as long distance telephony becomes developed, will interfere more and more with telegraphy, the one "will wax the other will wane." The law courts has decided that telephony is a part and parcel of telegraphy, and not something entirely novel—hence the Government will be compelled to take under its control the whole of its purchase. No doubt some hard words will have to be said as to the method of procedure the Government has pursued. The cynic will say great business tact has been shown. Perhaps it has; telegraphy was in the field; the country was almost fully equipped, and naturally the permanent officials desired to economise as far as possible. Hence the determination, we should say, to permit private companies to carry out the larger part of the initial work, and by experience find how to overcome the various difficulties which are always met with in the initial stages of introducing a new application of science.

The private companies have done their share of this initial work and have proved telephony a success. Now the Government will say, we shall assume control of the service, pay you a sum to be determined for your wires and apparatus, probably incorporate the employees as part of the Civil Service, and henceforth carry on the work as a State department. The private companies will not object, except to the price to be paid. The public will refuse to pay one halfpenny for prospective increase of returns, or for money expended in the experimental stage. It will justly be said that the experiments were out of our control, carried on with the facts of the case staring you in the face, were much too costly, and we shall not pay. On the other hand the companies will say theirs is a hard plight. The State would not of itself introduce telephony, would not even prove its practicability; and though the experience gained had been gained at a great cost, those who contributed towards the cost were quite willing so to do, having perfect faith that the returns would be in a very progressive ratio, and in the course of a short time would become so large as to amply repay all initial, even if excessive, expense. At the present moment telephony is, so to speak, "hired out" by the Government, so that two profits have to be paid by the user—the first to the company, the second to the Government. A business nation will not permit such a course to be pursued for many years. The control of the Postal Department is in the hands of some good business men, and there is no doubt that they will object to add to the liabilities of the department by paying, even a small sum, at the present time for patents which will shortly expire. In the ordinary course of business it is pretty easy to foretell that things will be allowed to go on much as they are till the expiration of these patents, when the Government will probably say to the telephone companies, now "the time we shall take this system into our own control. The price to be paid will exclude all consideration of initial cost of the patents to the companies, the argument being that, during the time that the patents have been running, the companies should have made a sufficient sum to have covered all their expenses and given them a handsome profit. It will be seen that there is hardly any means of reconciliation between these opposing interests. It is not the case of ordinary buyer and seller, but a case where the buyer already has a lien upon the property of the sellers.

Since the report of the deputation appeared, an explanation has been given, which shows our contention is probably right, and that there is no intention of Government immediately assuming the direction of telephony.

SAFETY FUSES.

The adjourned discussion on Mr. A. C. Cockburn's paper on safety fuses last week was noticeable for one feature—the unanimity with which speakers condemned the indiscriminate use of "safety fuses." It was agreed—shall we say it is agreed—that the major portion of

failures in electric light installations are directly traceable to fuses. Mr. Crompton hit the nail on the head when he admitted the necessity of the use of fuses, and that in order to comply with two antagonistic requirements electrical engineers must compromise in the matter of the position of fuses. Their proper position is at the root of the branch, but if placed in that position they are not within easy reach if anything goes wrong. The discussion witnessed some lively sparring—some speakers maintaining their experience of one and all fuses was that they were utterly unreliable; others as strongly maintaining that their experience pointed to the almost perfect manner in which fuses go off under the appointed circumstances. One gentleman would not trust fuses, but the apparatus which never failed in his hands, or under his observation, was Cunyngbame's magnetic cut-out. On the one hand "time" was said to deleteriously affect the fuse, on the other hand "time" was stated to have no bad effect. One set of speakers would not have "lead" or "tin," another stuck to lead or tin; one spoke up for the ordinary wire-shaped form of fuse, others staked their reputation upon "foil." Altogether the important lesson to be learnt from this discussion is that at present upon questions of practice all our doctors differ, and nothing can hardly be more beneficial to the industrial applications of electricity than these discussions from practical men upon such questions. They pave the way towards agreement and uniformity of practice.

DR. WOLLASTON.

William Hyde Wollaston, M.D., F.R.S., was among the most eminent cultivators of science during the early part of this century. He was born on the 6th August, 1766, and took the highest medical degree at Cambridge in 1793, being a student of Caius College. He subsequently commenced practice as a physician at Bury, but not meeting with much success he removed to London, and became a candidate for the appointment of physician at St. George's Hospital, but was unsuccessful. This was fortunate for science, as Dr. Wollaston was led entirely to relinquish the medical profession and to devote his whole energies to the pursuit of science. Dr. Wollaston died December 22, 1828.

Chemistry formed the chief subject of Wollaston's studies. He was the discoverer of two new metals, palladium and rhodium, but he did not confine his investigations to chemistry. His optical inventions alone have rendered the greatest service to both art and science. In 1793 he was a fellow of the Royal Society, of which he became secretary in 1806. For his Bakerian lecture, "On a method of Rendering Platinum Malleable," he was awarded one of the Royal medals.

The particular researches of Wollaston in the domain of electricity are best seen by reference to the memoirs of the Royal Society and in the *Philosophical Magazine*, as well as in the constant references made to his work in the earlier books of the century. Thus, in Dr. Rogets' work issued in 1831, under the auspices of the Library of Useful Knowledge, we find a number of references to Dr. Wollaston. He had devised an elementary galvanic battery, and had improved the construction of the, then, ordinary battery by surrounding each side of the zinc plate by copper. He promulgated original views regarding the electric light, the decomposition of water, the chemical source of electricity and electro-magnetism; and, perhaps with the exception of Sir Humphrey Davy, Wollaston was the most prominent figure in the scientific world at the birth of the 19th century, hence, we feel

ourselves justified in commencing this series of portraits of eminent electricians of this century with that of Dr Wollaston, which is given with our issue of to-day.

ELECTRIC LIGHTING OF TRAINS.*

There are three methods of train lighting in use, namely, by oil, gas, and electricity. As this paper is only intended to deal with the latter the first two systems will be passed over. The amount of light from each is in favour of gas against oil, and of electricity against gas. Incandescent

What I propose to speak of as the third method (patented May 17, 1886), is that which is now being tried for the first time, I believe, on the Glasgow City and District Railway. On the City and District Railway the circumstances under which the light is required are entirely different from almost all others, as it is specially required during the day and while the trains are in the tunnels only. These trains run in the open air the greater part of their journey, but have to pass through the tunnels from three to fifteen times daily; or, in other words, they are on an average somewhat over an hour in darkness. The arrangement for lighting each train as it enters the tunnel is as follows.—

lamps only are used in train lighting by electricity, the are light not being suitable. In using the incandescent lamps they are placed in each compartment, and generally take the place of the oil or roof lamp. There have been three practical applications of train lighting by electricity. In the first two the roof lamps are replaced by incandescent lamps, while in the third case they have not been interfered with. The first two methods are those which have been more or less used, while the third has just been tried

* Abstract of Paper read before the Philosophical Society of Glasgow, by Thos. P. Carswell.

A centre or third rail has been laid down from one end of the tunnel to the other, but is omitted in the open air, Fig. 2. It is formed of ordinary T iron, and is inverted and laid on insulators or supports, so that it stands 4in. or 5in. higher than the ordinary rail, as shown in Figs. 2 and 7. It is jointed together by small angle irons with four bolts, there being a small strip of sheet copper between the two, so as to help the contact, Fig. 3. The holes in the rail are oval, to admit of expansion and contraction, and it is held in position by iron center pins, which pass through the sides of the jaws or supports. At each end of the tunnel

this centre rail or inverted T iron is bent down to the level of the ordinary rails so as to form an inclined plane (Fig. 6).

The insulators or supports which are used are made of glazed fireclay, and have the central part or stem isolated from the base. The stem has two slots in it, one to receive the T iron and the other for the cotter or split pin to pass through. A small piece of roofing felt, soaked in oil, is laid in the slot on which the T iron rests. The lower part of base is made in the form of a trough, which is filled with oil to help the insulation, and is fastened to the sleepers by means of two coach screws.

By this method of fixing the centre rail it is always kept at the same height above the ordinary rails, and if the latter are raised the former is raised also as it rises with the sleeper. These supports are fixed about 5 feet apart, and as far as can be seen they stand very well.

Two contact makers or pulleys (Figs. 2, 3, and 7) are fixed to the framing of each carriage, at a height to correspond with that of the centre rail. Only one is actually required, but it is found that two give a steadier light, and where there are junctions to pass over both are required to maintain the connection. These pulleys are made of crucible cast steel and are 15 in. in diameter. They are hung on a centre so as to move in a horizontal direction, and have a spiral spring on the top of the axle-box, which allows it to rise vertically 3 in. or 4 in. Two side flat springs are fixed on the hanger or jaw in which the pulley works so as to keep it in a vertical position.

The current of electricity for lighting the lamps is derived from a large Crompton compound wound self regulating dynamo, having a potential at the terminals of 110 volts. This dynamo is always kept running, the positive lead being connected to the centre rail, and the negative lead to the ordinary rails. It is driven by the same engine as is used for lighting Queen street high level station. The leads are not connected directly with the centre rail, but to three Hedges' safety fuses in the engine room, designed to give way in case of a short circuit (Figs. 1 and 5).

The tunnel is divided into three circuits, namely, College to Queen street Station (low level), and Queen street to Charing Cross, and to Fimmieston, as shown in the last-mentioned figure. By this means, in the event of there being a breakdown in either tunnel, it can be switched off so as not to interfere with the other two. The lengths of the circuits are 748, 484, and 2,196 lineal yards respectively. The area of the centre rail increases as it leaves the dynamo, while the resistance to each circuit is the same. The estimated loss or fall in potential at the end of each circuit, with a train in it, was 10 volts, and it is found that at Fimmieston Station, which is 2,196 yards away, such is the case. It is possible to have two trains in two of the circuits and four in the other, or eight in all; and the cables leading to each have been arranged accordingly. Insulated cables, laid in crosstied troughing and filled with pitch, have been laid from the dynamo to the centre and ordinary rails.

The wires from the contact pulleys are connected to two 16 candle-power lamps, which have been placed in each compartment, fixed on either side of the ordinary roof lamp, so as not to interfere with it, and in order that the latter can be used when required (Fig. 2). These lamps, which are of the Swan type, are 25, 31, 50, and 100 volt lamps, also Brush 50 and 100 volt lamps, all of 16 candle-power nominal, but only one is lit at a time, the second being a reserve which automatically lights itself in the event of the first one failing.

Each circuit is formed in the following way. The positive lead to the lamps is connected to the two contact pulleys, while the negative is connected to the spring of the carriage. It will thus be seen that as soon as the train enters the tunnel the pulleys make contact with the centre rail, the current flowing from the dynamo through the centre rail and pulleys to the lamps, and returning through the springs and wheels of the carriage to the ordinary rail, and through it back to the dynamo again. On the train leaving the tunnel the pulleys run down the inclined plane of the centre rail, breaking the connection and so putting the lamps out.

As regards the power required for each train, it may be

said to be about 2,000 watts, or from two to three horse-power.

In order to prevent the rusting of the centre rail, and to keep it clean so as to make good contact, a steel wire brush is fixed on one carriage in each train. It is found that the brush makes better contact and gives a steadier light than the pulley, but, owing to the friction, the tear and wear would be too great to adopt it entirely.

It is found that the small "cut-outs" work best either with the 25 or 50 volt lamps, as they take more current, but even regulated and connected to a single 100 volt lamp they act well.

As already mentioned, the end of the centre rail at Fimmieston station, which is furthest away from the dynamo, is distant about $1\frac{1}{2}$ miles (2,196 yards); and at this point, with one train in circuit or 36 lamps, the potential is 100 volts, or that required to light the lamps.

The insulation of the centre rail is not quite perfect, there being a slight leakage, but it cannot be traced to any particular part, and it is practically unappreciable, being only about 3 amperes. This leakage may arise by the steam conveying the current to "earth," as on a dull day the centre rail is quite wet, and in the distance from the dynamo to Fimmieston the area exposed is no less than 840 square yards on one line alone, so that the leakage is not to be wondered at.

It will be seen that by this system the train, or rather each carriage, is lighted and extinguished on entering or leaving the tunnel—automatically, as it were. There are no connections between the carriages, so that the train can be broken up or shunted as usual, while the light is maintained whether the train is in motion or at a stand.

During the New Year holidays some of the trains were running with only one carriage fitted, while others had six or eight fitted and the remainder not.

During the passage of these trains through the tunnel the speed of the dynamo was nearly constant, and their presence in the circuit could only be detected by a slight hissing noise at the commutator brushes and a faint sparking, if any. This system has now been in use four months, and two trains have been running all this time, only being off one day weekly to be cleaned. The number of lamps in the two trains was, on an average, 60; and in the four months' lighting three of them have had to be renewed. Two of the three were broken maliciously, the outside globes having been broken also, while in the other the carbon filament gave way, having burned 100 hours.

Since this paper was read, twelve trains—or, in all, 89 carriages—have been fitted, and are running daily. Taking the running of the trains for six months the total number of lamp hours is 39,642. During this time it has been necessary to replace 44 lamps, so that the average life of the lamps has been 900 hours each, but as 11 of these lamps were broken maliciously by passengers in the trains, their actual life is 1,210 hours.

In this system the electric light is not used at night, the gas or oil lamps being still made use of, which are there to fall back on should a breakdown take place. In the other systems the electric light was used alone, and could be made use of any time, whereas in this it can only be had in the tunnels. Of course, it has the advantage of allowing the trains to be broken up (which is done sometimes twice a day) without having any extra couplings, and having the light only when required, without the control of any one. The cost of this system is less by a fourth than that of either of the other two, and fully a third less than that of gas, while the working expenses are much the same as the first two systems, but a third less than gas lighting.

Journal of the Society.—Part 69, Vol. XVI, of the Journal of the Society of Telegraph Engineers has just been issued. This part contains the discussion on Prof. Fleming's and on Prof. Ayrton's papers on measuring instruments; the report of the council to the sixteenth annual general meeting; and the paper by Mr. A. C. Cockburn "On Safety Fuses."

CORRESPONDENCE.

PARIS EXHIBITION, 1889.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: I am instructed by the President and Council of the Society of Telegraph Engineers and Electricians to request the favour of your giving as early an insertion as possible to the following notice.

"International Exhibition, Paris, 1889.

"In view of the interests of English electrical exhibitors, the Society of Telegraph Engineers and Electricians have appointed a committee to endeavour to ascertain their wishes and to make arrangements on their account with the French authorities. The Director General of the International Exhibition having requested the society to take part in the matter on behalf of the official administration, it is proposed shortly to address a circular to the principal firms interested in electric lighting and kindred pursuits, and to convene a meeting of gentlemen who are likely to take part as exhibitors in the forthcoming display.

"It is of extreme importance to British industries that they should be well represented on the occasion referred to, as without it there is danger of Continental opinion assuming that England has fallen back in the race for success in the alliance between Science and Commerce.

Yours, &c.,

"F. H. WEBB, Secretary.

"Society of Telegraph Engineers and Electricians,

"London, 1st February, 1888."

ELECTRIC LIGHTING.

[The following letter appeared in *The Times* of Tuesday, and a copy has been forwarded to us. It seems desirable that both those connected with the industry, as well as the public, should be kept cognizant with whatever is done in connection with Parliamentary action as regards electric lighting. - Ed. E. E.] :

To the Editor of the Times.

SIR: All who are connected with the electric lighting industry are looking forward with anxiety, yet with hope, to the forthcoming meeting of Parliament. I, therefore, crave permission to say a few words in your columns in support of the right of the public to have electric light, and of our claim to be relieved from the hindrances which Parliament, legislating at a time of unfortunate electrical speculation and excitement, thought fit to place in the way of the development of public central electrical lighting. The report of the House of Commons Committee on lighting by electricity, 1879, said, "Your Committee would observe generally that in a system which is developing with remarkable rapidity it would be lamentable if there were any legislative restrictions calculated to interfere with that development." The lamentable result of the legislative restrictions of the Electric Lighting Act, 1883, is that, while thousands of people are anxious to have electric light in their houses, there is not a single central station in the United Kingdom lighting the whole of any given area, its streets, public buildings, offices, and private houses, such as are common from New York to San Francisco, and are to be found at Berlin, Vienna, Dijon, Milan, Melbourne, and other places. Every first class steamer that is built is now supplied with electric light, clubs, banks, hotels, go to the expense and suffer the annoyance of having an installation on their premises, a few of the wealthy treat themselves to the luxury, but the hundreds of thousands of moderate means and the great majority of the well to do are not able to avail themselves of the beneficial discoveries of Edison and Swan, of Siemens and of Brush and others, but are fast losing hope of ever having electric light brought to their houses as readily and as cheaply as the dangerous and noxious, but useful and familiar gas.

The recent Parliamentary phases of the question are as follows:—

In 1886 Lord Rayleigh brought in a Bill in the House of Lords, which may be summed up by saying that it proposed that the electric light companies should be put upon exactly the same footing, alike as to restrictions and privileges as gas companies.

This Bill commended itself by its fairness, to a great number of impartial men, and as it was based on the opinion of a Committee of the House of Commons we had good hope of its passing. It would have been accepted by the electric companies and firms, many of whom would have to set to work under its provisions, and I have no doubt that if it had passed we should have had by this time a score of central stations in many towns distributing the electric light to willing customers.

In 1887 Lord Thurlow brought in a Bill. Lord Thurlow, from his connection with the industry, and from his position as chairman of the Electric Light Committee which assisted Lord Rayleigh in preparing his Bill, is familiar with the requirements of the public and the conditions on which electric lighting can be made to pay, and his Bill held the balance fairly between the trade and the public. Supported by the Prime Minister, Lord Cranborne, Lord Herschell, Lord Bramwell, and others, this Bill passed the House of Lords, but, alas! did not pass into law. The Marquis of Salisbury, in his speech in the House of Lords on this Bill, as reported in *The Times*, summed up the position so moderately and fairly that I hope you will allow me to quote an extract therefrom:—

"He did not dispute that this was a very suitable matter for local authorities to undertake if they were willing to do so, and he could quite imagine that in 1882 the Board of Trade and the local authorities, generally speaking, thought it would be a pity to allow companies to step into their place. But five years were passed away and they saw that the local authorities were not generally inclined to take this enterprise up. They were really putting the local authorities in the position of the dog in the manger.

They would not allow companies to enter upon an enterprise which they would not undertake themselves. He was inclined, in spite of the terror of the example of the gas and water companies, to go back to ideas of less restriction and of greater freedom in the matter, to allow enterprise to have its full swing, to remove all obstacles which had hitherto impeded it, and to offer terms not such as they thought the capitalist ought to accept, but which they felt by experience he would accept. So it might be possible, by giving rights which were generous and large, to procure for the public the full advantage of those scientific inventions which other nations had, and which now, by a restrictive policy, we prevented ourselves enjoying, without doing any good to those local authorities which were the subject of such tender care."

As the Prime Minister said, five years have passed and not a single local authority has established an electric lighting station; surely it is time to relieve us from conditions which prevent the public from having the light, and injure and cripple our business. It is a new thing in England that we should be prevented by legislation from availing ourselves of the discoveries of science, though they are acknowledged to be useful and beneficial, and though hundreds of thousands of people are anxious to make use of them.

Mr. E. Graves, engineer-in-chief of the Post Office and president of the Society of Telegraph Engineers and Electricians, in his presidential address, which was reported in *The Times* of the 13th inst., said that 42,368 persons were employed in the United Kingdom in connection with telegraphs, telephones, cable making, and allied businesses, of which number 5,000 were employed in connection with electric lighting, and he placed the probable number employed in connection with the above industries throughout the world at about 310,000. If an Electric Lighting Act rendering central stations possible is passed in 1888, it will give immense impetus to the electrical trade, and I am certain that I do not exaggerate the advantage which the working classes would gain when I say that within a couple of years of the passing of such an Act, some 100,000 men, women, and children would find healthy and profitable employment. This would be of great advantage in these days of depressed trade, and it is as unwise as it is unfair to persist in maintaining legislative restrictions which have punished the companies and the public without conferring any benefit upon the local authorities.

In America arc lighting is used for street lighting in

almost every town, and incandescent lighting is now quite general. I have been speaking this afternoon to Mr Edison's European representative, and I gather that the increase of incandescent lighting has been about 40 per cent in 1887 over its use in 1886. There are no less than 121 local Edison companies in the United States, the dividends in which vary from 6 to 14 per cent., and an American gentleman told me recently that he had shares in four electric companies, and had received dividends from the four averaging 11 per cent. on his investment.

I think, Sir, that however weak my pen may be, you will allow that I have made out a fair case for the intervention of Parliament. If you will give your powerful support to our oppressed industry, if Lord Thurlow will reintroduce his Bill, or better still if the Government would legislate on the subject, we may fairly hope that before long central stations for the distribution of the electric current may be established in many towns, giving work to thousands of mechanics, affording a safe investment to capitalists who would be content with the moderate dividends which would certainly be earned in supplying the public with electric light.

I am, Sir, your obedient servant,

S. FLOOD PAGE, Secretary and Manager.

Edison and Swan United Electric Light Company
(Limited), 13, Albert mansions, S.W., Jan. 25.

ON THE POSITION AND PROSPECTS OF ELECTRICITY AS APPLIED TO ENGINEERING.*

BY MR. WILLIAM GEIPEL, OF EDINBURGH.

In the present paper the author purposes confining his remarks to those branches of electric engineering which involve the employment of considerable power and are in some way connected with the use of dynamo machines. The principal of these may be treated under the four following heads:—

- I. Electric transmission and distribution of power.
- II. Electric locomotion.
- III. Electric lighting.
- IV. Electric metallurgy.

I. ELECTRIC TRANSMISSION AND DISTRIBUTION OF POWER.

In the near future this branch of electric engineering will probably occupy more attention and call forth more outlay of capital than either of the three others mentioned above; already, indeed, it is commanding a great deal of attention. Owing to its simplicity, the ease with which an electric motor can be applied to any purpose requiring power, and its high efficiency, it is certainly an approach to an ideally perfect system of transmission. No greater contrast can be imagined than the difference between the position of electricity in this country and in America. On the other side of the Atlantic, although the science of electricity is much behind, the practice is far ahead of our own. European science has supplied an agent, the value of which has been recognised by American engineers; and now in the United States the applications of electric motors are already rivaling and will soon excel in importance the application of electricity for lighting purposes. It is to be remembered, however, that there, owing to the high price of coal, the use of steam-power is a more serious consideration than here: they have also in many places abundance of water-power which can be utilised by electric transmission. Notwithstanding these differences, there is in our own country an almost unlimited field for the employment of this mode of transmitting power cheaply to a distance, and of distributing power generated at a central station to a number of users in the neighbourhood.

Were it not for the cost of the dynamos and motors, electricity would supersede to a great extent the use of belts and shafting. In large works, where high speeds are required and the demand for power is variable, the efficiency of belts and shafting is very low indeed. As much as 25 per cent. of the power may be absorbed by the shafting when

the full number of machines are in use; and in such a case with half the machines in use the loss of power rises to nearly 50 per cent., while in the extreme of driving only a single machine even 99 per cent may be lost. With electricity, on the other hand, no power is being used in keeping the transmitting medium in motion, the conductor being stationary, the loss takes place only whilst power is actually being used by the motors, each of which drives its own machine. In fact the percentage of power lost in the transmitting medium becomes smaller as the amount of power transmitted is reduced, which is exactly the converse of what happens with belting and shafting. For the sake of illustration and comparison, let it be assumed that a loss of 25 per cent of power would take place in the electric conductor when the full load is on, although in reality the loss would never be above 10 per cent, and need not be more than 5 per cent. Then with half-load the loss would be 12½ per cent., and so on; and with one machine possibly one-tenth of 1 per cent. might represent the loss in the conductor. When it is remembered in how many cases the average load in a factory is less than half the maximum, it is evident that this point is one demanding the greatest consideration. In New York, where a large number of motors are supplied with current from the electric-light mains, it has been found by experience that on an average less than one-third of the whole number of motors are in use at any one time.

The depreciation of the electric conductors is comparatively small, but whether the saving of renewing belts and of lubricating shafting would not be counterbalanced by the wear and tear of motors, is a question to be settled by individual experience. The advantage, however, of getting rid of shafting, thereby obviating the necessity of additional stability in the building and doing away with constant lubrication, and the further advantages of saving the space and light absorbed by belts, and of the ease with which the conductor can be shifted to suit any desired alterations in position of machines, are also very important matters.

The distribution of power by electricity from a central station to small users will, in the author's opinion, form in many towns a larger business than the lighting. Both can be done from the same mains and generators, just as is the case with gas; it is merely a question of economy and convenience as to whether gas or electricity should be used. The encouragement of small industries has long demanded some cheap means of obtaining power in small quantities, say, from ½ to 25 h. p. The gas engine has not altogether met the requirements of small establishments, although needing but little attendance, for the first cost of even a small engine is high, and the amount of gas consumed is large. Moreover the speed is generally irregular, owing to the intermittent impulse, which is more especially noticeable with light loads, and a considerable amount of wear and tear takes place in the valves and working parts.

An electric motor can be started and stopped at will with the greatest ease, it requires the smallest amount of attention, occupies the minimum of space, and can be placed in almost any position. An ordinary shunt-wound motor will run at an almost constant speed, with a maximum variation of only 5 per cent. from running light to fully loaded, this fact was first pointed out in an interesting paper in the *Philosophical Magazine*, for January, 1886, by Mr. Morley, who has done much valuable work in the perfecting of the modern dynamo machine. He has kindly sent the diagram exhibited, showing the result of some tests of a Victoria motor for change of speed under variable load, which illustrates the remarkable constancy of speed attained. This exceedingly close regulation was obtained by using a simple shunt motor of suitable construction, and without any accessories such as the many forms of governing devices to which so much attention had previously been devoted. The result shows that such a motor possesses a practically perfect power of self control, not only over its rate of speed with varying load, but, what is of equal importance, over the energy absorbed by it: for it helps itself, as it were, to only such an amount of energy as will enable it to deal with the work imposed on it. Another advantage in the use of shunt motors is that they act as generators when themselves driven by any extraneous power, without any complication of switch gear such as is required with a series

* A paper read before the Institution of Mechanical Engineers, February 2, 1888.

motor. This fact was first pointed out by Sir William Siemens in a paper read before the Society of Telegraph Engineers, 3rd June, 1880. In such a system, where railways, lifts, &c., are being worked by motors, the current generated by descending trains or loads might suffice at times to supply the rest of the motors with sufficient current for their work, without absorbing any current from the dynamo; at any rate it would reduce the amount of current required to be supplied by the dynamo. The first cost is also small compared with that of a gas engine. A 1 h.p. motor will cost £20 against £100 for a gas engine. The cost of running a gas engine is about one penny per horse power per hour for gas alone; the same power generated by a dynamo driven by an efficient steam engine costs only about one farthing, current being supplied from street mains just as gas is.

As small steam engines are being superseded by gas engines wherever the outlay for the latter can be afforded, the competition in regard to small powers lies between gas and electricity, and steam may be left out of the question. There is of course a limit above which steam becomes the cheapest; and probably 10 h. p. may be taken as about that limit in this country. In Boston, in the United States, where some hundreds of motors are supplied with electricity from central stations, they range from $\frac{1}{2}$ to 15 h. p., and are working lifts, printing establishments, small machine shops, and watch-making, tailoring, boot making, and similar industries. Their working seems to be highly appreciated; and the author understands the users would be willing to pay even 25 per cent. more for them, in consequence of their convenience and regularity in working. In Geneva, within a radius of a mile and a quarter, there are no fewer than 175 motors at work, varying from $\frac{1}{2}$ to 70 h. p., supplying power to small workshops and for other purposes, the electric power being obtained from dynamos and turbines which are driven by water power derived from the Rhone. The installation is paying its way, and is about to be largely increased. At the Falls of Niagara plant is being put down to distribute power obtained from the falls to neighbouring towns, including Buffalo which is 20 miles distant; the amount of power is stated at 15,000 h. p., of which 10,000 h. p. is contracted for at £3 per horse power per annum for power and lighting purposes in Buffalo.

As an interesting example may be mentioned a 6 h.p. motor recently erected by the Brush Company of Cleveland, Ohio, in a printing establishment, where it was connected with the regular arc light circuit. It takes the place of a 10 h.p. steam engine, which had sometimes come to a standstill under its load. It drives about 70 to 80 feet of shafting, three cylinder presses, four platen presses, one large paper-cutter, and one very heavy lift; and by a 4in. belt carried up through three floors it also drives three ruling machines and four paper cutters. It does its work splendidly, and its motion is steady and regular. It has proved to the proprietor's satisfaction that printing offices could well afford to employ electricity instead of steam, even in cases where the first cost might be more. In many other towns in America, where the electric light mains are within reach, the number of motors already in use is very great; within two years 5,000 motors have been supplied by one firm alone, and the author understands that the Brush Company are turning out as many motors as dynamos.

In some places in this country, and more especially in Lancashire, it is customary for power to be supplied from a large steam engine to neighbouring buildings, which are let out as separate workshops. In such instances, however, the power supplied is more frequently above than below 10 h. p., and probably it would not pay to introduce an electric motor. Still it should not be forgotten that in renting these workshops considerable inconvenience may be incurred as regards the locality of the premises for the manufacture; moreover, the rent is often disproportionately high.

Many schemes have been propounded for distributing power in manufacturing districts by means of steam, compressed air, and water pressure, each of which is in use to a somewhat limited extent, and as all of them have been known long enough, it may seemingly be inferred from their limited employment that there is not much to recommend

their extended use commercially. With steam, the condensation in the pipes causes loss of pressure, and results in wet steam being supplied to the engines. Compressed air cannot efficiently be worked expansively, and is attended with loss of heat in the compressor. Water pressure commonly involves using the maximum power, whatever the work required. Besides these prominent faults of the three several methods, what is of the greatest importance and common to all three is that the generating plant has to be used almost exclusively for supplying the power, and cannot be utilised for other purposes in addition, whereas with a central electric station the engines and dynamos serve to generate current for lighting purposes also at night.

Collieries.—In collieries electricity will be largely adopted in the near future. For underground hauling, pumping, ventilating, and drilling, it can readily be applied with an efficiency double that of compressed air. With a well-arranged installation, 75 per cent. of the brake power of the engine will be utilised on the shaft of the motor.

For hauling and pumping, wire ropes or rods are the greatest competitors of electricity, which obviates the following disadvantages in connection with them: Chance of breakdown through strain; wear and tear; mishap to guides through falls of roof or dirt; trouble and expense of oiling the guides, and room required at pit mouth or at bottom for engine, pulleys, or levers, or other gear. As the tendency in mines in this country is towards a reduction of working hours, the question of mechanical haulage becomes most important, because horses must be fed whether at work or idle, and the cost of haulage by horses therefore increases as the working hours become reduced.

For ventilating and drilling, compressed air is, perhaps, most largely used; and one of the great points in its favour is that the exhaust is available for supplying fresh air to the miners, and for driving out the foul gas after the firing of shots. But the cost of the compressed air machinery is heavy, as is also that of the pipes for conducting the compressed air from the compressor to the place where it is used. The cost of electric plant is somewhat less, and the efficiency is very much greater; while by using old haulage ropes as conductors the cost of this item is rendered very small.

At Trafalgar collieries, in the Forest of Dean, there is an interesting instance of pumping on a small scale. A Gramme machine driven at bank supplies current to a motor in the mine 800 yards distant from it. A current of 15 amperes at 100 volts, equal to 1,500 watts or 2 h. p., is found sufficient to work the pump, which is double-acting, 5in. diameter and 8in. stroke, and runs up to 70 revolutions or 35 gallons per minute, lifting about 90ft. The entire installation cost £250, it has been working about four years, and has given so much satisfaction that additional plant has lately been put in at a distance of 1,650 yards from the pit shaft for lifting 120 gallons per minute 300ft. high, the distance between the pump and the generator being 2,200 yards. A double throw pump with 9in. plunger and 19in. stroke is driven at 25 revolutions per minute by spur gearing reducing 6 to 1, the small pinion being driven by a belt from the motor. Current is conveyed to the motor by a conductor composed of 19 wires No. 16 S.W.G. (0.065in.) thick, giving 0.065 square-inch total sectional area, insulated and carried on earthenware insulators; an old 4in. wire-ropes serves for the return circuit. The efficiency obtained throughout is only 35 per cent.; but as much as 649 h. p., or 22 per cent., is lost in the engine alone, which is an old one. The cost of engine and electric plant and pump complete was £774, without pipes. The weekly cost of maintenance is given as follows by Mr. Brain, the colliery manager:

Engineers, half time	£1 8 0
Men underground, full time	2 9 0
Small coal consumed, say 36 tons at 1s	1 16 0
Oil, waste, and sundries	0 7 0
Interest and depreciation, say 15 per cent.	1 17 0

Total per week £7 17 0

Total per annum £408, showing a yearly saving of £470 of the water power that was superseded. The cost of the water raised is 0.02 penny per h. p. per hour, and 1.8 pence

per 1,000 gallons. At the same collieries a 6 ft. fan is also being worked by an electromotor at 1,800 yards distance from the generator.

(To be continued.)

ELECTRICAL MEASUREMENTS, ESPECIALLY AS APPLIED TO COMMERCIAL WORK.*

BY PROF. WM. A. ANTHONY.

(Continued from page 97.)

We need, however, instruments for measuring currents in the ordinary and about dynamo machines, and a great variety of instruments called ammeters have been constructed for these purposes. In general, such instruments consist of a coil of wire carrying a magnetic field which is compared with an artificial field produced for the purpose, or the magnetic force developed by the coil in the presence of some other magnetic field is compared by some known force. To be more explicit, one form of ammeter consists of a coil which tends to deflect a needle against the artificial field of a permanent magnet. The accuracy of these instruments depends upon the constancy of this opposing field. But the permanent magnet does remain constant, and these instruments, therefore, need to be frequently calibrated. Another form of ammeter is one in which the coil acts upon a mass of soft iron, developing a force which is opposed by a coil spring. Here the accuracy of the instrument depends upon the constancy of the spring and upon the constancy of the deflection of the little mass of iron.

And here let me say that a magnetic field is not of itself a force. To have force there must be two magnetic bodies, and the force exerted depends as much upon the one as upon the other. A coil of wire conveying a current develops a magnetic field, but before a force can be produced something else that can develop a magnetic field, as a mass of iron, a magnet, or another coil of wire carrying a current, must be brought within the range of its action. If this second body can only produce a weak field, then only a feeble force will be produced. Moreover, the force will vary with every change in this second body, and if the current in the primary coil remain constant.

Speaking of this fact, of the necessity of two magnetic bodies to develop a magnetic force, reminds me of a question often asked in regard to extracting particles of steel that have become lodged in the eye. Would not a sufficiently powerful magnet extract them? I always tell the questioner that the most powerful magnet in the world could exert but a small force upon a particle of steel. If you can loosen the piece of steel, a magnet is a very good means of taking it out of the eye, but a small magnet does as well as a large one. I was once asked by a gentleman that he had known of a sewing needle that was drawn down in the flesh of the leg being drawn out by the operation of a powerful magnet. I remembered how little the most powerful magnet can exert where a sewing needle is the body attracted, and thought to myself that the statement needed confirmation. Some of you will remember that there was proposed to build the 1,000 feet iron tower in Paris, and I predicted that all the loose iron articles, knives, pointers, etc., etc., in the Paris, to say nothing of wagon-tires and horse-shoes, would come rushing pell-mell to the base, in consequence of the tower becoming a great magnet by the earth's induction. He notwithstanding the prediction, I do not think I should be the first to have my keys and pocket knife this side the water if I were going to visit Paris after the erection of the iron tower.

Let us return to our ammeter, the little mass of iron is attracted by the coil, because it becomes itself a magnet. If it becomes a strong magnet, it is attracted strongly; if it becomes a weak magnet, it is attracted feebly. Its magnetic strength will not be the same under all circumstances, and the force exerted by the coil is therefore, not always the same when the same current is flowing. I have recently recalibrated an Ayrton and Perry instrument of the permanent magnet type, and found its constant had changed 16 per cent. since last March. Last spring I calibrated two other ammeters at the same time, and found one to read 5 per cent. fast, while the other was nearly as much slow.

Do not understand from this that I consider these instruments of little value. They are the best we have. What I want to impress upon you is the importance of frequent comparison of instruments with others known to be standards. Theoretically, the best ammeter is one in which the force exerted between the coil and the same current is opposed by gravity. Here the force developed depends only upon the current which it is desired to measure, and the opposing force is the one force at all times, and that does not have to be watched and tested, but is the same to-day as yesterday, and can be trusted to be the same to-morrow as to-day. Such an instrument would, therefore, give accurate indications. (Thomson instruments exhibited.) There are, however, practical difficulties in the way of construct-

ing such an instrument for the measurement of large currents. One of the coils must be movable, and it is difficult to take a large current to and from it without imposing some constraint upon its motion. We still want for commercial use a really good ammeter for measuring large currents, one that we can trust as we trust our scales for weighing merchandise, to give correct indications for weeks and months and years.

I have dwelt thus upon these instruments, which measure rate of flow, because, as I have already said, some of the most important effects of electric currents depend upon this element. There are cases, however, where we wish to know the total quantity of electricity flowing in a given interval and care nothing for the rate of flow at any given instant during that interval. For instance, we are furnishing a house with incandescent lights. It is important to know the quantity of electricity furnished per month. The unit in which we measure electricity in such cases is the quantity conveyed in one second by a current of one ampere. This is the coulomb already spoken of. It has not been found easy to construct a reliable coulomb meter. The Edison Company use a meter in which the current deposits zinc upon a zinc plate. This is a very good method for the laboratory, but it is difficult in practice to fulfil all the requirements for completely reliable meters. At least, so far as I can learn, neither the consumers nor the company seem to be perfectly satisfied. The new coulomb-meter exhibited and described by Prof. Forbes about a month ago, at a meeting of the Electrical Engineers in New York (and in this Hall), depends for its action upon the development of heat in a wire by the flow of the current. The wire, in the form of a flat spiral, is placed below a little windmill. The flow of electricity in the wire heats it, and so sets up air currents that cause the little windmill to revolve. A train of wheel-work, connected with the windmill, actuates the hands in front of a dial. Thus the instrument registers the flow of electricity as a gas meter registers the flow of gas. Practical experience only can tell whether this instrument will fulfil all the requirements.

But the measurement of currents or of quantities of electricity is but a small part of what is required in electrical measurements. Potential in many cases is quite as important an element as strength of current or quantity. To go back to our analogy of a flowing fluid, we know that pressure is necessary to bring our gas to the burners, but so long as it is sufficient to supply gas in proper quantity and gives us a good light, we do not trouble ourselves about it. It is the business of the gas company to maintain the required pressure, and they must adjust by a pressure gauge. It is the chemical energy of the gas that gives the light, and the energy due to the pressure is too small an item to be considered. But suppose we are supplying steam or compressed air for driving engines, the pressure is now a more important item. The power used is the product of pressure by volume of steam used per second. Pressure is, therefore, one of the items that the consumer pays for. Where electricity is supplied for any purpose, the energy which the consumer pays for is the product of potential by quantity. Varying either factor varies the energy delivered, and measurement of potential is, therefore, as important as measuring quantity or current. The unit in which we measure potential is based upon the relation just stated, that the product of potential by quantity gives the electric energy. The absolute unit potential is the potential under which the absolute unit current performs the absolute unit work in unit time. A true volt is 100,000,000 absolute units.

Before taking up the methods of measuring potential, let us consider the other electrical units and their relations to those already defined. The farad, the unit of capacity, is the capacity of a body which contains one coulomb when charged to a potential of one volt. At a potential of two volts the same body would contain two coulombs, but its capacity is still one farad. It is as though we were to define a gallon as the capacity of a vessel which holds one pound of air under a pressure of one atmosphere. Under two atmospheres the same vessel would hold two pounds, under half an atmosphere half a pound.

The ohm is the resistance of a conductor in which the volt maintains the current of one ampere. These are the true definitions of these units, and need to be carefully considered when our measurements involve the determination of electric energy. To see how this is important, let us consider the actual measurement of a resistance. To measure a resistance upon the basis of the definition just given is a very difficult operation. So difficult that even after twenty-five years of such measurements we do not feel very certain of the value of the ohm. In 1862 the British Association appointed a committee to determine the ohm and construct standards. After some years of labour standards were produced, consisting of coils of wire supposed to have the resistance defined as the ohm. From these resistance boxes are constructed and resistances are measured by comparing the unknown with these known resistances. This is a very simple matter, and can be quickly and accurately done. The difficulty of measuring a resistance upon the basis of the definition of the ohm is shown by the fact that later determinations indicate that the British Association standard, now known as the B. A. ohm, is about one and three-eighths per cent. too small. The Paris Congress, recognizing the difficulty of arriving at a positive value on account of the dif-

* Abstract of a lecture delivered at the Franklin Institute.

crepancies between the results of different observers, adopted a standard, the resistance of 106 centimetres of mercury one millimetre in cross-section, to be called the *legal ohm*. This, according to the best of our present knowledge, is about one-quarter of one per cent. too small. They further decided that the unit current should retain the value assigned by the British Association, and adopted as the *legal volt* the potential difference that maintains a current of one ampere in the legal ohm. The legal volt is, therefore, about one quarter of one per cent. too small.

Now, suppose we have measured a current in amperes and the potential in legal volts, multiplying, we obtain the energy, but, since the unit in which potential is measured is too small, the result is too large, and must be reduced one-quarter of one per cent. to obtain the true energy. I think it unfortunate that the legal standard was not made 106.25 centimetres of mercury, for it seems certain that this amount, to the fourth figure at least, is the correct value of the ohm. If the legal ohm had been so chosen, computations of energy based on measurements in legal units would not have been in error by more than one-tenth of one per cent., and for all ordinary purposes corrections would have been unnecessary. The measurement of a potential in legal volts is not a difficult matter. It consists in measuring the current maintained in a conductor whose resistance is known in legal ohms. A standard instrument for such a purpose would be a delicate galvanometer whose coils consisted of many turns of wire of a known high resistance—of high resistance, because the instrument must take so little current from one point to the other as not appreciably to alter the difference of potential between them. (Experimental illustrations.) A multitude of voltmeters for commercial measurements are on the market, most of them being instruments similar to the ammeters already spoken of, but with coils of very fine wire in which a current, proportional to the difference of potential, is produced. In fact, the ammeters and voltmeters often look so much alike that they could not be distinguished, except for the words "volts" and "amperes" on the dial. These instruments are as likely to change as the corresponding ammeters, and require the same precautions as regards calibration.

But there are other ways of measuring potential that do not depend on the measurement of a current. If two plates are connected, one to one point and the other to another, the difference of potential between which is wanted, these two plates, when brought near together, attract each other with a force proportional to the potential difference. This force of attraction is, however, very small, and requires an extremely delicate instrument to indicate it, until the potential difference is 400 or 500 volts. (Thomson's voltmeter shown.) Another method of measuring potential is to balance the unknown against a known potential. The difficulty in applying this in practice is to obtain a reliable standard. Voltaic cells afford the best means of obtaining a fairly constant potential difference, but only under very exact conditions are these potentials sufficiently uniform to be accepted as standards. (Potentials of cells measured.) A gravity cell that had been in use some time gave a deflection of 46. One set up about eight hours before the lecture gave 64, and one set up just at the beginning of the lecture gave 65.

(To be continued).

ON SOME INSTRUMENTS FOR THE MEASUREMENT OF ELECTROMOTIVE FORCE AND ELECTRICAL POWER.*

BY J. A. FLEMING, M.A., D.SC. (MEMBER), AND C. H. GIMMINGHAM.

(Concluded from page 92.)

[Fig 6 shows collar referred to in paragraph 3, p. 91, and Fig. 7 shows needle carried by movable coils, see paragraph 2, p. 92.]

We have also constructed, on this type, a Wattmeter. In this case the fixed coils (now called the current coils) are wound with thick wire, and so arranged that the four coils can be joined up in series or in parallel. From a separate pair of terminals the current is conducted into the thin wire coils, which are the movable coils, and constructed exactly as for the voltmeter, only with a higher resistance. (See Fig 8.) In using this Wattmeter for measuring the power taken up, say, in an incandescence lamp, the following method of joining up should be adopted. (Fig. 9.)

Let $M^1 M^2$ be the mains, and let L be the lamp. The lamp should, as usual, be put in series with the thick wire coils, T . The fine wire coils, F , should have their terminals joined, not to the two terminals of the lamp, but to the terminals of the lamp and the thick wire coil as joined in series. The thin wire coil thus measures the potential at the extremities, not of the lamp,

* Paper read before the Society of Telegraph-Engineers and Electricians.

but of the lamp and thick wire coil in series. The reason is as follows:—Suppose the thick wire coil to have a resistance of .01 ohm and the thin wire coil to have a resistance of ohms, and apply this Wattmeter to measure the power consumed in two lamps, each of 8 candle-power, and requiring, say, 2 watts—but in one case let the lamp be a 100-volt lamp taking 2 ampere, and in the other a 10-volt lamp taking 2 ampere. If the fine wire coil is joined in parallel with the lamp, also, in the case of the high-volt lamp, since the resistance is 500 ohms, the lamp will take two-thirds of the whole current flowing through the thick coil—in other words, the current which flows through the thick coil is not that flowing through the lamp, but through the combined resistance of lamp and fine wire coil. However, the same wattmeter is applied to measure the power in the low-volt lamp, then, since the hot resistance of this is only 1 ohm, the lamp will get 1000/1005ths of the current flowing through the thick coil. It follows from this that whereas 10 lamps consume exactly the same power, yet, in the first case, the current in the thick coils, which is that which actuates and of the factors in determining the reading of the wattmeter, is half as great again as it should be. It would be found in the case of the high-volt lamp the wattmeter reading was 30 watts, and in the case of the low-volt lamp 20 watts, although both lamps actually take the same power. If, however, the terminals of the voltmeter, or movable or fine wire coil, are joined, as shown in Fig 9, then the current in the thick wire coil, exactly that through the lamp, the error in the electromotive force part of the measurement is then only dependent on the fact that the thick wire coil has an appreciable resistance; if only .01 ohm, the error made in the electromotive force part of the measurement is only .1 per cent., even in the case of a low-volt lamp, by assuming the potential at the extremities of the lamp and thick coil in series as equal to that at the terminals of the lamp.

FIG. 6.

Unless the resistance of the current coils is vanishingly compared with that of the high resistance or movable coil, the above method of joining up the wattmeter does not give the true rate of dissipation of energy in the lamp or other circuit under consideration.

Let us examine the theory of the instrument a little closely. Let R (Figs. 10 and 11) represent the resistance of the thick wire or current coils, and let r represent the resistance of the fine wire or volt coils, and let p stand for the resistance of the lamp or other circuit in which the dissipation of energy is measured. Given the ends of these thick and thin wire coils, we may then join them up to the lamp in either of two ways, as shown in Figs. 10 and 11.

What we actually do in the use of a thick and thin wire electro-dynamometer, employed as a wattmeter, is to take the products of the strengths of the currents in the thin wire coils respectively, by measuring the electro-dynamic attraction between these circuits when held in certain positions. If, however, the circuits are joined up to a lamp as in Fig. 10, although the current in R is equal to the current in the lamp, yet the current through r is not proportional to the difference of potentials on either side of the lamp, but is by an amount which depends on the ratio of p to R . W_1 represents the true watts taken up in the lamp under measurement, and W_2 represents the observed watts by the dynamometer on the assumption that it has been calibrated for one per cent. of very high resistance compared with R , then

$$W_2 = W_1 \frac{R+p}{R}$$

for W_1 is made up of two factors—one a number proportional to the current in R , which is the current through the lamp, and another factor which is proportional to the difference of potentials over all between the outside terminals of lamp and coils R .

This last is greater than the potential difference on either side of the lamp, in the ratio of $R+p$ to p .

Next, let the fine wire coils be joined to the terminals of the lamp as in Fig. 11. The current in r is now proportional

potential difference on either side of the lamp. The current in the thick wire coils is not, however, identical with that through the lamp, but equal to that through the lamp and fine wire coils together. If i stand for the current through the lamp, and C for the current in the thick wire coil R , then

$$i = \frac{r}{r + \rho} C,$$

and accordingly, if, as above, W stand for the true watts

FIG. 7.

expended in the lamp, and W_2 for the watts as observed on the dynamometer, we have the relation

$$W_2 = W \frac{r + \rho}{r} \quad (11.)$$

From equations (1.) and (11.) we have

$$W_1 \rho = W \rho + W R,$$

$$W_2 r = W r + W \rho;$$

$$\text{hence,} \quad W_2 \frac{R}{r} = (W_2 - W) (W_1 - W);$$

$$\text{or,} \quad W_2 - \left(\frac{r}{r + R} \right) (W_2 + W_1) W + \left(\frac{r}{r + R} \right) W_1 W_2 = 0.$$

The solution of this quadratic equation gives W .

It is not difficult to show that this quadratic equation always has a real positive root, since r is greater than R , and W_1 and W_2 are positive quantities. We arrive, therefore, at this result: If any given wattmeter of this type has been calibrated on a lamp or other circuit of which the resistance is very great compared with the thick wire or current coils, supposing the connections made as in Fig. 10, then the observed readings of the wattmeter, when used with any other lamp or circuit, will

FIG. 9.

we give the true watts expended in that circuit, but give a value which is rather too high, and of which the error will depend on the value of the three resistances, R , r , and ρ . We can, however, eliminate the error, and obtain a number proportional to the true rate of expenditure of energy in the circuit, by taking two observations with the high resistance coils joined up respectively as in Figs. 10 and 11. If these readings are called W_1 and W_2 , the insertion of these in the quadratic equation above will enable us to find a value (W) which is proportional to the real watts, and that without knowing the resistance of the lamp being tested.

In the construction of a wattmeter of this type it is evidently important that the current coils should have as low a resistance as it is possible to secure in comparison with that of the movable or voltmeter part. In our wattmeter the fine wire coils are of German silver wire, and have a resistance of 1,000 to 1,200

ohms. The thick wire or current coils are of the highest conductivity copper; and in the instrument designed as a lamp wattmeter, to read direct from 1 to 400 watts, have a resistance of about .1 or .2 ohm. It is intended to issue wattmeters of three grades: one reading from 1 to 400, the next from 10 to 4,000, and the highest from 100 to 40,000, and suitable for electromotive forces of 50 to 250 volts.

FIG. 8.

In the wattmeter above described the scale is, of course, a scale of equal divisions. In the form of instrument adapted for lamp measurements, the circular scale is divided into 400 divisions, and each division represents 1 watt. By means of a wattmeter and voltmeter of the above description, all the four electric elements of a lamp can be measured at once. Let the wattmeter be joined up as indicated in the above diagram (Fig. 10), and let, in addition, the terminals of the voltmeter be connected to the points A and B, the voltmeter then reads the potential difference of A and B, and the wattmeter reads the consumption of power between A and B. If W be the reading of the wattmeter and V that of the voltmeter, the quotient of W by V gives the current through the lamp, and the quotient of the square of V by W gives the hot resistance of the lamp. We have designed an instrument which shall be a combination of watt- and voltmeter, and enable the two measurements of potential difference at extremities of a circuit and power consumed in that circuit to be simultaneously measured, and therefore to give at once the current in the circuit and the hot resistance. In this instrument the fixed coils would be wound compound, with two coils on each, one thick overlaid by a thin wire winding.

FIG. 10.

FIG. 11.

The connections of the fine wire windings on the fixed coils are so arranged in conjunction with a switch, that when the switch is turned one way the solenoids have, as ordinarily arranged, a N pole at the centre of each, but when the switch is turned the other way this pole is abolished. Hence, if a current flows through these fine wire windings in series with the movable coils, then, according as the switch is set one way or the other, the current will operate the instrument or not, and that without changing its resistance or affecting the current in the movable coils. Let then the thick wire coils be traversed by a main current, and the thin wire coils by a current derived by connecting their extremities to the ends of the conductor traversed by the current through the thick wire coils. The electro-magnetic force operating to displace the movable part of the instrument will be the resultant of two forces—one due to the product of the strength of the current in the thick coil and the current in

the movable coil. This product is proportional to the power consumed in the conductor. Secondly, in addition, there is a force due to the action of the current in the fixed fine wire coils on the current in the movable coils in series with them. This force is proportional to the square of the current strength or to the square of the volts at the ends of the conductor. Hence, if the switch is turned so that both thick and thin wire fixed coils are operative, the electro-magnetic force on the movable coils is proportional to the watts added to the square of the terminal volts. If W be the power consumed in the conductor, and V the potential difference at its extremities, then this reading of the instrument will be proportional to $A W + B V^2$, when A and B are instrumental constants. Next, let the switch be turned so as to render the fine wire coils electro-magnetically inoperative, although not altering the resistance of the total fine wire circuit. In this case the reading is simply proportional to the power consumed in the conductor, or to $A W$. We have therefore, by two readings, the power consumed and the terminal volts of the conductor or circuit, and hence, by simple division, the current and hot resistance.

In this method of measuring a current, the movable part of the instrument is not traversed by any but a very small current, and hence the difficulty generally experienced in getting a large current in and out of a freely-moving circuit has not to be combated. In considering these instruments as permanent standards, the question obviously arises as to the permanence and perfect elasticity of the steel spring. The steel chronometer spring is made of the very best and most carefully-tempered steel. The use in chronometers justifies the statement that, when not strained beyond the limits of elasticity, and when not kept in strain for a longer time than necessary to take a reading, the elasticity is perfect. There is only one caution which should be taken in using these instruments. After taking a reading, the central index-hand should be turned back to zero before putting the instrument away. If the voltmeter is closed up and put on one side, with a permanent twist upon the spring, then a slight deformation of the spring may result, which will in time disappear, but not immediately. The elastic modulus which is brought into play in this use of a spiral spring is somewhat similar to that which is operative when a beam is bent. The spiral is not drawn out, but is twisted round and bent slightly into a smaller radius. Under prolonged strain a very slight deformation occurs, which disappears gradually on the removal of the stress, and this deformation is a function both of the stress or strain and the time under which the elastic body is submitted to that stress.

On this point we may quote the experience of Prof. W. Kohlrausch, who, in a paper in the *Elektrotechnische Zeitschrift* (see *Electrician*, March 25, 1887), gives the result of prolonged experiments on the employment of spiral springs in measuring instruments. The effect of age, judging by observations on a brass spring extending over a period of seven years, may be completely neglected. Continuous and prolonged deformation produces a small amount of permanent set, so that the spring, when released, does not return to its original position, but this does not actually alter the indications of the instrument if the readings are taken from the new zero thus formed. Steel is in this case less affected than German silver. Oft-repeated but intermittent deformation, as exhibited by a spring of 90 convolutions and 2½ in. long being stretched, so as to change from a length of 3 in. to 9 in. 200 times per minute for 400 minutes, introduced no sensible alteration into its subsequent indications.

An increase of temperature of 18 deg. Fahr. raised the indications of a Siemens torsion galvanometer about one-tenth per cent., so that the reduction in elasticity of the spring is apparently almost equal to the decrease in moment in the magnet. Further experiments on loaded springs confirmed this conclusion, and showed that steel was again to be preferred to German silver. We think, therefore, that there is sufficient evidence to lead us to believe that the selection of a highly-tempered steel chronometer spring as a means of weighing the electro-dynamic attraction of coils traversed by currents will not be found to lead to appreciable errors.

Instruments with the suspension we have here designed and used are not very well suited for marine use, but we are engaged in arranging a mode of suspending the movable coil which will render the instruments independent of any levelling when in actual use.

POSTAL AND TELEGRAPH REGULATIONS.

On Friday last an influential deputation of merchants and manufacturers in Wolverhampton waited upon Mr. Raikes, M.P., at Oxley Manor, near Wolverhampton, the residence of Mr. Staveley Hill, M.P. The members of the deputation called the attention of the Postmaster-General to several anomalies connected with the postal and telegraph regulations. They complained that orders to manufacturers and others sent by the half-penny post were charged letter-rate if any note was added. They desired that documents of a commercial character—orders, invoices, shipping instructions, bills of lading, &c.—

should go through the halfpenny post. Owing to the varied practice, some post offices passed them and others charged them letter rate. The charge for sending telegrams from post offices through the telephone to their destination was complained of as being too high.

Mr. Raikes, in reply alluded to the charge for registered telegraph addresses, and spoke of the decision of the department in the case of Sir R. Samuelson, who made representations on the same subject on behalf of the Associated Chambers of Commerce last April. It was explained that, while the original fee of £1. 1s. was not unreasonable, the annual payment of 6s. afterwards was unequal to the cost incurred. The department did not propose to take any steps in the matter because cypher messages not only caused delay in their despatch, but also delayed the delivery of fully addressed messages. The department was inclined to believe that the advantages gained by persons who had registered addresses were gained at the expense of the general public. Then as to the question of surcharges on invoices, &c., sent through the halfpenny postage, the whole question turned on what was the actual definition of a letter. It seemed to him that anything which was "particular" was in the nature of a letter and anything which was general was in the nature of a circular. A mere invoice would pass through the halfpenny postage, but the notes and annotations added to them, either in writing or printed matter, were regarded as being in the nature of a letter. The practice varied very much. He should, however, be very glad to hear any suggestions which would place matters on a more regular and uniform basis. The specific complaint in one case submitted to him was that a firm of merchants had printed on a circular order, "The above order for samples most urgent, say first post certain when can be sent." That note was of a particular character, and in the nature of a letter. The department was very anxious to facilitate trade, but he could not hold out any hope of interfering with the penny postage, which was the sheet anchor of the postal revenue. The telegraphic branch was a losing one to the extent of half a million last year, and the department also lost on the carriage of newspapers to foreign countries. The Post Office made a profit of about 2½ millions per year on the whole, and that was a very valuable source to which the Chancellor of the Exchequer looked for revenue towards defraying the national expenditure. He had no statistics by which he could say whether the department realised any profit on the commercial letters alone. With regard to the sale of postcards at 6d. per dozen, that was a matter requiring consideration, and as to the issue of halfpenny commercial envelopes, that was a matter which should receive attention. Then, with respect to the telephone, he agreed that the position of telephoning was unsatisfactory, and was due to various causes. He thought one of the principal causes was the generosity of his predecessor, the late Mr. Fawcett, whose statements had been interpreted in the direction of an interference with the rights claimed on behalf of the telephone companies. He thought that before long steps must be taken to place telephony on the same footing as telegraphy, either under the control of the Government or entirely with private enterprise. He did not think that the present system could be justified. With regard to the payment of £5 per year for the right of having telegraph messages sent to a private house from the post office through the telephone, he did not think that that was an extravagant sum for gentlemen who wished the luxury. However, the question was one which had better be left with the Government to deal with. He pointed out that in this country the facilities for telegraphing were much greater than on the Continent, and that was perhaps one reason why so much use was made of the telephone on the Continent, and why telegraphs were more popular in this country. In conclusion, he said he should be very happy to receive suggestions which would assist the department in making the regulation clearer as to what was the nature of a letter. That was the main principle to be recognised, and the department desired to cause the least inconvenience to the general public. He quite agreed that there were disadvantages in the delivery of telegrams to places situated at long distances from the post offices. He could not, however, promise that anything should be done this year, nor could he promise that he would be in office next year. He fully appreciated what had been placed before him, and should be glad of any suggestion which would assist in placing the whole system of telephony in this country on a satisfactory basis.

The deputation then thanked Mr. Raikes, and withdrew.

LEGAL INTELLIGENCE.

GAULARD AND OTHERS v. SIR COUTTS LINDSAY AND CO. AND FERRANTI.

This was an appeal from a decision of Mr. Justice Kekewich. The action was brought by Messrs. L. Gaulard and J. D. Gibbs and the National Company for the Distribution of Electricity by Secondary Generators (Limited) against Sir Coutts Lindsay and Co. Limited and Sebastian Ziani de Ferranti to restrain the infringement of five letters patent of the plaintiffs. On the 21st of November Mr. Justice Kekewich, in the matter of a petition presented by Ferranti for revocation of one of the patents, made an order giving the plaintiffs liberty to apply at the Patent Office to amend the specification of that one of the letters patent. The plaintiffs afterwards moved for liberty to apply at the Patent Office to amend the same specification by way of disclaimer, correction, or explanation, and that in the meantime the trial of this action might be postponed, and that the specification, when amended, might be used in evidence at the trial on such terms as the Court might think fit. The application was made under section 19 of the Patents, Designs, and Trade Marks Act, 1883, which provides that in an action for infringement of a patent, and in a proceeding for revocation of a

patent, the Court or judge may at any time order that the patentee shall, subject to such terms as to costs and otherwise as the Court or judge may impose, be at liberty to apply at the Patent Office for leave to amend his specification by way of disclaimer, and may direct that in that case the trial or hearing of the action shall be postponed." Mr. Justice Kekewich was of opinion that it would be unreasonable to allow a postponement of the action as to all the patents. And he said that if the plaintiffs would not accept the defendant's offer, that the plaintiffs should discontinue the action as to the one patent and pay the costs as to that, the motion must be refused with costs. These terms being refused by the applicants' counsel, the motion was accordingly refused with costs. The plaintiffs appealed.

Before the conclusion of the arguments the plaintiffs consented to the order which they asked being made upon the following terms (which the defendants were willing to accept).—That the plaintiffs should pay all the costs of the action up to the present time, and that they should not claim any relief in respect of anything done by the defendants before the amendment of the specification. The defendants to have liberty to amend their defence and particulars of objection.

Lord Justice Cotton said that a long and learned argument had taken place upon the construction of section 19; but, as both parties had assented to terms, he would give his judgment very shortly. In the case of "Bray v. Gardner," Mr. Justice Stirling had given liberty to the plaintiffs to apply for leave to amend their specification on the terms that the amended specification should not be used in the pending action. The Court of Appeal said that liberty to make such an application ought not to be given under section 19, unless it could be given without injustice to the defendant. But the Court did not say that the terms then imposed ought to be imposed in every case. In the present case Mr. Justice Kekewich thought the other terms should be imposed. But the appellants had now offered terms which his lordship thought would do complete justice in the present case. This offer had not been made in the action below. As the plaintiffs were asking for an indulgence, they must pay the costs of this application in both courts.

Lord Justice Lindley agreed. He did not think there was any difference between "Bray v. Gardner" and "Allen v. Doulton." In every case the Court must see what would be right and just.

Lord Justice Bowen also concurred. He desired to point out that what had been said by Lord Justice Cotton in no way narrowed the construction of the Act. When an act of Parliament had vested a discretion in the Court, the Court never wished to limit that discretion by laying down rules as to the way in which it was to be exercised. The discretion was given to the Court. The language of section 19 appeared to indicate that terms were to be imposed by the Court, if it should think the justice of the case required that they should be— that is, in order to prevent injustice being done to the one party by the indulgence which was granted to the other. That was exactly what was said down in "Bray v. Gardner."

PROVISIONAL PATENTS, 1888.

JANUARY 20.

924. Improvements in measuring and recording apparatus. James Greve Lorrain, Norfolk House, Victoria Embankment, London, W.C.
925. New or improved measuring and recording apparatus. James Greve Lorrain, Norfolk House, Victoria Embankment, London, W.C.

JANUARY 21.

932. Improvements in the construction of portable primary batteries adapted to medical and other appliances. Robert Henry Thomas, 1, Hillmarton road, Camden road, N., and Benjamin William Warwick, 134, Highbury-hill, N.
933. Improvements in contact regulators for electric clocks. Ferdinand Boshardt, 8, Quality court, London. (Louis Bouchet, France.)
977. Improvements in apparatus for signalling upon railway trains in motion. James Ashton, 4, South-street, Finsbury, London.
980. An improvement for the construction of electric battery cells for lighting or other purposes. William Balch, 32, Elberton road, Clapton Park, E.
981. Improvements in electric "call" signal apparatus. Charles Spratt, 24, Southampton-buildings, London, W.C.

JANUARY 23.

994. Improvements in controlling railway signal levers by the application of electricity. William Frederick Burleigh, 106, Canterbury New-road, S.E.
995. Improvements in interlocking apparatus for railways. William Frederick Burleigh, 106, Canterbury New-road, London, S.E.
1009. Improvements in dynamo-electric machines. John Hubert Davies, 3, Barry-terrace, Westbourne square, Paddington, W.
1016. An improvement in electrical transforming apparatus. Alfred Muls Taylor, 28, Southampton-buildings, Chancery-lane, London, W.C.
1024. Improvements in and connected with electric coils. Laurus Simon Magnus Pyke and Harry Theodore Barnett, 433, Strand, London.
1029. Improvements in rotary galvanic batteries. Alfred Wundrich, 18, Buckingham street, Strand, London, W.C.

JANUARY 24.

1055. An electric safety apparatus. Reginald John Jones and Arthur Wright, "Lily Lodge," Vale of Heath, Hampton, N.W.
1090. Improvements in switches for making and breaking electrical circuits. Sigward Bergmann and John Thomas Dimpster, 23, Southampton-buildings, Middlesex. — Complete specification.
1091. An improvement in or connected with counting or recording mechanism and electricity. Alfred Aird, 166, Fleet-street, London.
1100. Improvements in electrical brazing and soldering. George Downing, 8, Quality-court, Chancery-lane, Middlesex. (E. Blas, Germany.)
1103. Improvements in apparatus for communicating signals on railway trains. Patrick Daley, 28, Southampton-buildings, Chancery-lane, London, W.C.
1106. Improvements in the means or appliances for treating sewage by electrolytic action and for disposing of the deposits thereof. William Webster, Junior, 28, Southampton-buildings, Chancery-lane, London, W.C.

JANUARY 25.

1128. Improvements in galvanic batteries. Alphonse Alexandre Fortin, 53, Chancery-lane, London.
1173. Improvements in electric induction apparatus. Bernhard Schittauer, 18, 36, Kingham street, Strand, London.

JANUARY 26.

1177. Improvements in means for supporting or suspending elements in electric batteries. Eason Edwin Mandeville, 31, Roseman street, Clerkenwell, Middlesex.
1210. Reversible chlorine batteries. Emile Annetoli, 62, Loughborough park, S.W., Surrey. (Pierre Anatole Pichet and Albert Louis Camille Nodon, France.)

COMPLETE SPECIFICATIONS ACCEPTED.

JANUARY 17, 1887.

747. Means or apparatus to be employed in the application of electricity to propel vehicles on roads with or without tram or other rails. Frank Wynne, 46, Lincoln's Inn-fields, W.C.

JANUARY 21, 1887.

949. An electrical switch or circuit closing and interrupting device of improved construction. Gerald Perival, 30, Old George's-street, Cork.

FEBRUARY 16, 1887.

2419. Improvements in dynamo-electric machines. Ferdinand Boshardt, 8, Quality-court, London. (August Louis Hilaire-Desobus, France.)

MARCH 26, 1887.

4546. Improvements in dynamo electrical machines in combination with motor engines. Charles Denton Abel, 28, Southampton-buildings, Chancery-lane, London, W.C. (The Firm of Siemens and Halske, Germany.)
4553. Improvements in electric telegraph apparatus. William Dickenson, 24, Southampton-buildings, London.

APRIL 2, 1887.

4914. Improvements in switches for making and breaking electric circuits. Robert Daniel Smilie, 87, St. Vincent street, Glasgow.

MAY 25, 1887.

7530. Improvements in electrical transformers. John Grace Statter, Norfolk House, Norfolk street, Strand, W.C.

NOVEMBER 18, 1887.

- 15,868. Improvements in dynamo-electric machines and electro-motors. William Main, 109, Fleet-street, London.

NOVEMBER 22, 1887.

- 16,032. Improvements in electro-motors and dynamo-electric machines. William Main, 109, Fleet-street, London.

SPECIFICATIONS PUBLISHED.

- 15,344. Automatic switch and governor for electric lighting purposes. A. M. Clark (The Elektrotechnische Fabrik Cannstatt), & Co.
- 16,865. Coupling up batteries for lighting, &c. L. R. Davies and M. Shearer, & Co.
- 17,120. Dynamo-electric Machinery. R. E. B. Crompton and J. Swinburne, & Co.
3998. Applying electric light for photographic purposes. F. J. Chary, & Co.
- 15,093. Type-printing telegraphs. A. Le N. Foster and W. S. Steggs, & Co.
- 16,406. Telegraphic transmission, &c. P. B. Delany, 11d.
- 16,424. Telegraphic instruments. W. P. Thompson (Baker), & Co.
- 16,476. Telegraph, &c., poles. W. Bayliss and E. Jones, & Co.

CITY NOTES.

The Consolidated Telephone Company. We are informed that Mr. J. H. Buckingham, of Wimpole street, Cheapside, has joined the Board of the Consolidated Telephone Construction and Maintenance Company.

Western and Brazilian Company.—The traffic receipts of the Western and Brazilian Telegraph Company for the week ending January 13, after deducting one-fifth of the gross receipts, payable to the London Platino Brazilian Company, were £2,875.

Anglo-American Telegraph Company.—The directors' report of this company for the last year ended 31st December states that the total receipts from the 1st July to the 31st December, 1887, including the estimated balance of £18,323. 6s. 8d. brought forward from the

last account, are estimated at £113,283. 6s. 5d. This amount, however, is subject to revision upon settlement of the accounts for the year with the Paris New York Telegraph Company. The traffic receipts show an increase of £9,460 as compared with the corresponding period of last year. The total expenses of the half-year, including repair of cables, &c., as shown by the revenue account, amount to £49,688. 8s. 1d. Interim dividends of 7s. 6d. per cent. on the ordinary stock, and 15s. per cent. on the preferred stock, were paid on the 1st November last, absorbing £26,250, leaving an estimated balance of £37,344. 18s. 4d., out of which the directors recommend the company to declare final dividends of 10s. per cent. on the ordinary stock and 20s. per cent. on the preferred stock, amounting to £35,000, making a total distribution for the year ended the 31st December 1887, of £1 7s. 6d. per cent. on the ordinary stock, and £2 15s. on the preferred stock, leaving an estimated balance of £2,344. 18s. 4d. to be carried forward to the next account.

NOTES.

Stockholm.—The Royal Palace is lighted throughout by electricity.

Dividend.—The Taunton Electric Lighting Company, at their first annual meeting on Monday last, declared a dividend of 5 per cent., and a balance was carried over.

Paris Municipality. At a recent meeting the Municipal Council of Paris, after a long discussion, voted the sum of one million of francs, which the Commission of the Budget had decided to devote to the creation of a municipal service for electric lighting.

Electric Lighting in Paris.—The Continental Edison Company has just completed the electric lighting of the Grand Hotel by an installation of 800 incandescence lamps, which are located in the grand saloon, the Zodiac saloon, the reading rooms, and the restaurant, and are worked by ten Edison dynamos.

Aerial Conductors. According to the researches of M. Gaglielmo, of the Turin Academy, no loss of electricity takes place through moist air, surrounding an uncovered wire, until the difference of potentials reaches 600 volts. Above this critical tension the loss augments with the voltage and with the degree of humidity of the air.

A Prospective New Chemistry.—Dr. Grunwald, of Prague, has arrived, by spectroscopic evidence, at a conclusion already supported by the names of Mr. Norman Lockyer and Mr. Crookes, viz., that certain of the supposed simple bodies or elements are in reality of a highly complex nature. His researches have extended to hydrogen, oxygen, carbon, and magnesium.

Glasgow Exhibition.—The electric lighting of this exhibition, as is well known to our readers, is in the hands of the Brush Company, who are utilising the plant recently used at Manchester for a similar purpose. The dynamo shed forms an annexe to the machinery section, and is 118 ft. long by 100 ft. broad. The lighting arrangements are being actively carried forward.

Electricity in Finland.—Electric lighting and the telephone have been taken up with some enthusiasm in Finland. Two little towns, with a population of 2,000 each, have adopted electric lighting; whilst the telephone is in operation not only in the towns, but in the country. Helsingfors and Abo, at a distance from each other of 112 miles, are connected by a telephonic wire.

St. Pava.—The President of the Van Depoele Electric Tramway at St. Catherine's states that the electric cars work in double what the horse cars did when running over the same line, that the business of the road has already increased by 35 per cent., that five electric cars do the work of eight horse cars. Also the cars are kept cleaner, and the drivers and conductors take an interest in keeping them so.

The Telephone in Russia.—Telephonic lines are being established at Rbinak, and in the arrondissement of the same name. The municipal hospital and several private houses are already in connection, and the Juravlef factory, at two versts from the town, is in communication with its office at Rbinak, whilst the suburban residences of several merchants are being connected with their business premises in the town.

Board of Trade License.—Notice is given in the *Gazette* that application has been made by the Kensington Court Electric Lighting Company, under the Lighting Act

of 1882, for license to produce and distribute electricity, power to make charges, to acquire lands, to construct works, to make arrangements with local authorities to open streets and lay electric lines, over a certain district defined in the license, around their station.

The Electric Light in Mines.—The *Forges et Houillères* Company of the Aveyron is about to establish electric lighting in all the works at one of their most important concessions situated at Combes. The motive power required will be supplied by the steam engines already in use. If the result of this experiment is satisfactory, the same system of lighting will be adopted in all the other concessions of the Company.

Electric Gas Lighters.—The lighters in which a platinum wire is raised to incandescence by the current from chloride of silver cells are well and favourably known to the public; but Messrs. Woodhouse and Rawson have improved upon this form, and have introduced a lighter in which the required current is obtained by a magneto generator worked by a spring. The advantage of this form is immediately seen. It involves no battery or chemicals. The only question, perhaps, is how will damp affect it?

Cost of Electric Lighting.—The following comparative estimates of the cost of lighting Chicago are taken from a report by Prof. Barrett. It must not, however, be assumed that these figures are true everywhere. The cost of gas is not the same at one place as in another, and unless the cost of gas is given figures are apt to be misleading:—

	No. lights.	Candle power.	Cost per year.
Gas	3,273	52,368	\$12,351
Arc lights	750	1,500,000	\$7,180
Incandescent lights	3,273	98,190	\$9,346

Society of Antiquaries.—We are pleased to learn that the Society of Antiquaries has availed itself of the advantages offered for the utilisation of the Royal Society's gas engine plant during free hours, and has installed a total of 110 16 candle-power lamps throughout its premises. The spare power is stored in 33 of Drake and Gorham's improved type cells capable of discharging at 60 amperes for about nine hours. Switchboards of the same firm's latest design, and fitted with the patent ring contact switches, are employed for governing the main circuits.

Royal Meteorological Society.—The council of the Royal Meteorological Society have arranged to hold at 25, Great George-street, Westminster (by permission of the Council of the Institution of Civil Engineers), on March 20th to 23rd next, an exhibition of apparatus connected with atmospheric electricity, including lightning conductors, photographs of lightning, and damaged objects. The committee will also be glad to show any new meteorological instruments or apparatus invented or first constructed since last March; as well as photographs and drawings possessing meteorological interest.

Subways.—Our American contemporary, the *Electrical World*, calls attention to one of the dangers of subways through the leakage of gas in places where the gas-mains are adjacent to subways. It is almost certain that sooner or later the subway will be filled with gas, and unless great care is taken accidents will arise, either by the gas being inflamed, or, as was the case at Philadelphia, a man working in the manhole being—shall we say—poisoned. Our friends connected with the gas journals are very quiet over many of the dangers which exist in the usage of gas, and which do occasionally bring about bad results. We have referred to one of them.

Electric Lighting in Spain. The Schuckert Company are carrying out the electric lighting of the Royal Opera at Madrid, in accordance with the decisions of the municipality. The installation will comprise 1,500 incandescence lamps and a dozen Kriak arc lamps. The Bilbao municipality have voted for the electric illumination, by means of 32 arc lamps, of the main promenade in the town. The motive power will be supplied by the steam engines actually in use at the waterworks. The progress of electric lighting in Spain is evidenced by the fact that the little town of Albacete, with a population of only 20,000, is to be lighted with 16-candle incandescence lamps; many of these being also supplied to private individuals.

Early Telegraphy. In the *Civil Engineer and Architect's Journal* of the date January, 1847, there occurs the following paragraph:—"The South-Eastern Railway Company have exhibited their confidence in this invention by making preparations to lay down an electric telegraph from Folkestone to Boulogne." It seems certain, after all that has been written, the early history of telegraphy is not well known. The unfortunate part is that those who could give interesting and authentic history are passing from us one by one, leaving the details untold. Who can give any information about this scheme of the South Eastern Railway? Was it the original idea which culminated in the success of Brett, Crampton, & Co., or was it another scheme altogether?

Trade Conferences.—A series of conferences of the representatives of various trades and handicraft industries is now being held at the Finsbury Technical College. These began last autumn with two general conferences on technical education. The third conference, which was for the cabinet-making trade, and was attended by a large and very representative audience, was held on January 14th last. The next conference, which is for bricklayers, is to be held on Wednesday, February 15th, when Mr. James Rowlands, M.P., will preside, and a paper on the Technical Education of Bricklayers and Brickcutters will be read by Mr. H. W. Richards. This will be succeeded on the 18th inst. by another conference of carpenters and joiners, under the presidency of Mr. W. R. Cremer, M.P.

Smelting by Electricity. Although numerous inventors have attempted to substitute electricity for coal and coke in metal smelting, nothing practical has yet come of these attempts. Siemens, Huntingdon, Cowles, and others have experimented with the dynamo, and the Cowles process for obtaining aluminium is, perhaps, the only commercial application as yet successful. There should be room for good work in this direction. As far back as the British Association meeting in 1847, attention has been directed towards the utilisation of electricity in these processes. Sir R. Inglis, in his address at this meeting, referred to successful laboratory experiments, but dwelt strongly upon the fact that the process which proved successful in the laboratory and in dealing with ounces was not necessarily successful in the manufactory and in dealing with tons.

Polarisation.—F. Strenitz, continuing his experiment on polarisation, finds that with silver the oxygen plate is found to attain maximum polarisation when the E.M.F. of the cell is equal to that of three Daniells, the polarisation of the hydrogen plates is at a maximum when an E.M.F. of two Daniells is used, it decreases when a greater E.M.F. is employed, but rises again and becomes equal to the first maximum for an E.M.F. of nine Daniells. The explanation given is that the deposition of metallic silver on the cathode,

which is greater the greater the intensity of the current, by increasing the surface decreases the relative strength of the current and the amount of the polarisation; so that although a small E.M.F. produces maximum polarisation with clean plates, a very considerable one is required to attain the same maximum with plates thickly coated with silver.

Sprague Motors.—The use of this motor has been adopted at a sugar refinery at Boston. The cars run all day, and the load averages 10 tons per trip. Horses used to do the work, and the trip occupied 15 minutes, with electricity it occupies five minutes. The gross load is 15 tons, including the car. We could fill our note columns with confirmation concerning the successful use of electrical traction in America, but we are tempted to ask, What is the use? One of the oldest, most experienced, and open-minded of tramway engineers, discussing electrical v. horse traction, put the case of the directors of companies very pointedly. He said: "They know now where they are, forage is cheap, and they can pay from 5 to 7 per cent." What more do you want? We have not great expectation that the older lines will change, but what about newly projected lines?

Submarine Telegraph Cables. In the sitting of the Budget Committee of the Reichstag on February 8th, during the discussion of the proposed purchase of the telegraph cables between Borkum and Lowestoft and Groetsiel and Valencia, Dr. von Stephan, the Prussian Postmaster-General, declared that it was intended to make a considerable reduction in the telegraph rates between Germany and England after the agreement on the subject had come into force, which would be on January 1st next. The charge for the Grundtaxe, at present amounting to 40pf., would be abolished, and the rate per word, which is at present 20pf., would be reduced to 16pf. The Minister added that the British Government would take over the Borkum-Lowestoft line, and establish direct communication with London and the more important towns of England. The agreement was unanimously approved by the committee.

The Electric Light in Belgium.—The trial installation of the electric light at the National Bank, Brussels, has been so satisfactory that it has been decided to dispense with gas altogether, and the new illuminant is to be introduced in the depôts and treasuries by M. Leon Gerard. The establishment of a syndicate for the development of electric lighting, which would include the name just mentioned, as well as that of M. Mourlon and the *Société Industrielle d'Electricité*, is spoken of in Brussels. Elsewhere in Belgium great activity prevails in this direction. Amongst the installations in progress may be specially mentioned that at the zinc rolling mills of the Vieille Montagne Company, at Tieff, with 24 arc and 100 mean descent lamps, that in Melhaerts Sugar Works at St. Trond, and that in the spinning mills of M. Albert Oudin at Dinant, all three being carried out by the firm of Bouckaert at Brussels.

Edmondson's Calculating Machine.—Some of our readers who have much to do with figures, and especially with the multiplication and division of large numbers, might do well to follow the example of Mr. T. A. Edison, who has just obtained one of the new circular Arithmometers for use in his laboratory at Orange, New Jersey. The new machine possesses important advantages over those of less recent construction, multiplying and adding, or multiplying and subtracting in one operation, in the time which would be occupied in multiplying alone, i.e., in so short a

time that even a practised computer can scarcely find the required logarithms in the same period. In many cases it may be an important advantage to relieve the brain of the tedium of computation, and to substitute for this the new arrangement of the figures and the working of the machine, which is in reckoning what the sewing machine is in needlework.

Belief in Electric Traction. "I expect," says the president of a tram line at Washington, "to see horses altogether banished from the street car service in the next few years, and their place taken chiefly by electricity." George Westinghouse, jun., says: "The results of a comparatively short experience in the use of electricity as a motor for surface railway cars has been such as to demonstrate beyond question its immense superiority for this purpose over any other known method of applying power. Every consideration of efficiency, convenience, and economy, not to speak of humanity, urges the substitution of mechanical for animal power upon the numerous street railway lines of the country, at the earliest practical moment; and in the contest for superiority in the various more or less successful methods of applying mechanical power to this purpose, such as the steam locomotive, the traction cable and the electric motor, the last named is at the present moment generally admitted by those most competent to judge to be distinctly in advance of all competitors."

Electric Lighting in France. The electric light has just been introduced in the offices of the Administration of State Railways, Rue de Châteaudun, Paris. A plan of electric lighting for the town of Versailles is under consideration. Motive power would be derived from the machine at Marly, this portion of the scheme necessitating an interesting application of the electrical transmission of energy. The matter is in the hands of a company which is being established to work electrical apparatus produced at the Oerlikon workshops. The Thomson-Ferrand Gas Company has just carried out an illumination of the electric light at the theatre in this town; it will comprise 150 Edison lamps. The Montpellier theatre is to be lighted by electricity. In virtue of a recent decision of the municipal council of this city, a contract has been entered into between the municipality and M. Victor Kopp for the lighting both of the *salle de spectacle* and of a portion of the highway at Montpellier. The motive power is to be transmitted by means of compressed air.

Cam Grano Salis. A waste product of an important chemical process, says the *Electrical World*, is a liquid as colourless as distilled water, but twice as heavy. This is named by an inventor at the Mechanics' Fair, Boston, to be a valuable element in the storage battery. He has discovered that when used in place of the usual solution in the storage battery, it increases both its efficiency and its capacity for retaining its charge to an enormous degree. Not only this, the inventor was almost thunderstruck at the effect of a further experiment with the liquid the other day. "Mixing it with a certain substance whose nature he keeps secret for the present, and charging a bottle of it with electricity from a dynamo, the result has been a brilliant glow of the entire contents, a light which has lasted undiminished ever since. Thus, if the inventor's hopes are borne out, the result will be an electric lamp that may be freely transported anywhere, lasting for a long period without charging, and substantially, perhaps, perpetual." We are unpleasantly familiar with the location,

"the nature of which is kept secret for the present;" but possibly there may be some foundation for the above statements.

Notes on American Electric Tramways.—Mr. Ransom, writing on the comparative cost of steam, horse, cable, or electricity, takes a simple road, six miles long, with 24 cars, a speed of six miles an hour, and running 20 hours out of 24. This would require 48 horses on the lines and 192 in the stables, costing, with harness, initially about 38,400dols. The initial cost for electrical plant he estimates at 26,500dols., for cable plant 35,000dols., and for comparison these figures may be put—

A motor plant of horses	costs ...	\$38,400
" " electricity	" ...	26,500
" " cable apparatus	" ...	35,000
" " steam	" ...	1

With regard to the road, the estimate is for horse road single track per mile 9,000dols.; electric varies according to system from 10,000dols. to 23,500dols.; cable roads from 30,000dols. to 110,000dols.; steam 9,000dols. If old roads have to be adapted to the new traction, the cost of adaptation is given for a six mile road: for cable 265,200dols., for electricity 70,500dols., for steam 10,000dols. In conclusion, Mr. Ransom says: "In original cost, expense of operating, cost of maintenance, outlay in applying to old roads, steam distances every other mechanical system."

Bath and Taunton. We stated some time since that an effort would be made to introduce the electric light into Bath, a number of influential citizens having avowed their willingness to co-operate to that end. In more than one quarter we have heard a wish expressed that the efforts of these gentlemen may be successfully accomplished ere the visit of the British Association in September next. We are not in a position to give any information on the question, or to state what progress has been made, but from the position and character of the gentlemen interested we have reason to believe that they "mean business." Taunton has won considerable credit by the introduction of the electric light. Speaking at a public dinner there the other day, the Hon. Percy Allsopp, the member for the borough, said that Taunton had made such rapid progress, and had become so well known, that he hardly ever took up a morning paper without seeing some account of a visit that had been made by some scientific body or well known corporation, for the purpose of seeing what Taunton alone throughout the whole of the West of England possessed. The Mayor and Corporation were to be congratulated upon having made the town of Taunton famous, not only in Somerset, but throughout England. They had succeeded in successfully introducing a most wonderful scientific improvement in the shape of the electric light, and the town after dark presented a most bright and cheerful appearance. Taunton was the first to successfully deal with one of the most difficult problems that a Corporation had to face.—*Bath Chronicle*.

Electrical Lighting Plants.—Messrs Siemens and Halske and Messrs Ganz and Co. have designed portable electric lighting plants. The former was described and illustrated in a recent number of *Industries*, the latter is said by the same paper to differ from the former in that Messrs. Ganz employ an alternating current dynamo, and put all the eight arc lamps in series. For incandescent lighting they employ a small transformer. Power is supplied by an 8 h.p. portable engine working at 60lb. pressure, and making 130 revolutions per minute. On a platform projecting back over the fire box, and therefore over the

driver, is mounted an alternating current machine, driven direct from the fly wheel at 750 revolutions per minute. The engine and dynamo are protected by a roof against the weather. The car contains eight alternate current arc lamps suspended from flexible bars so as to protect them against jolting on the road; also a small four-wheel trolley, on which are mounted two drums containing a mile and a quarter of suitable wire; also two water butts, insulators, earth anchors, a screw jack, and an assortment of tools. The lamp posts are of wood, and are on brackets fixed to the outside of the car. The total cost of the plant was about £830. All the circuits are carried overhead, and at a recent trial one superintending engineer, one driver, one lineman, and eight labourers, erected the plant and began lighting up in seven hours, reckoned from the time when the engine and car were unloaded from the railway trucks. After finishing work, the whole of the material was again replaced, and the engine and car loaded, in four and a half hours.

City and Guilds Institute. The following evening course of instruction has been arranged. A special course of four lectures on the mechanical engineering involved in the design and manufacture of dynamo machines and motors, will be delivered by Prof. John Perry, M.E., D.Sc., F.R.S., once a fortnight on Thursdays at 7 p.m., commencing February 16th, together with drawing office work on the same subject on the alternate Thursday evenings from 6 to 9 p.m. It will be necessary to state the electric and magnetic rules which are now adopted by the best engineers in the construction of continuous and alternating current machines, switches, &c., but the course will be made, as much as possible, a practical course on the mechanical engineering of dynamo machines and motors. The following gives the subject of the lectures:—

February 16th.—Continuous current dynamos and motors in use described. Electric and magnetic rules which are now adopted, as to sizes of iron and the winding. The iron and other materials used. Where the mechanical engineer's usual methods of working must be modified. Journals.

March 1st. Simplicity of design. The usual causes of a breakdown. Use of machine tools. General questions of strength of parts. Armatures. The division of metal. Insulation and winding of wire, &c., on the field magnet and armature. Lasting power and strength of joints.

March 15th.—Forces to which the wound wire is subjected. Influence of these on design of armature. The driving of dynamos direct and by gearing. Driving from motors. Commutators and brushes, their design, insulation, strength, wear and manufacture. The electric transmission of power.

April 15th. Alternating current machines in use. Electric and magnetic rules. Design and manufacture in the past, and probably in the future as compared with that of continuous current machines. The past and probable future of dynamos.

Physical Society, Glasgow University. Among other interesting points referred to in Mr. Andrew W. Meikle's paper on Friday, Feb. 3, the following comparison of a number of Sir William Thomson's balances, independently standardized by the electrolysis of copper sulphate solutions, were quoted. Two centi-ampere balances standardized eight months ago were at that time found to be in absolute agreement when compared with each other. These two instruments have been compared from time to time since that date with a view of checking their relative constancy, and are still in absolute agreement. Two deci-ampere balances, A and B, were also referred to. One of the above mentioned centi-ampere balances was used

A, while the constant of deci-ampere balance B was taken from three separate electrolytic experiments which were in very close agreement, the first differing from the second by $\frac{1}{100}$ per cent. and the second from the third by $\frac{1}{50}$ per cent. These two balances A and B when compared together showed a difference of $\frac{1}{10}$ per cent., while deci-ampere balance A is still in absolute agreement with the centi-ampere balance used to determine its constant. As regards the larger instruments, the results were equally satisfactory. Taking in the whole set of the seven standard instruments, the largest variation of constant for one instrument when compared with the one next above it was observed between the ampere and deci-ampere balances, and was then only $\frac{1}{50}$ per cent. Thus, at the time of writing there were in the Physical Laboratory of the University of Glasgow a series of standard instruments capable of measuring from half of a centi-ampere to 500 amperes, all of which were, practically speaking, in perfect agreement.

Accumulators on Trams. Electrical engineers will no doubt be called upon frequently to draw up plans and estimates for tramway work, both with accumulators and direct working, hence the following figures of Mr. Huber will be of interest. He estimates that the energy required to be stored in the cells in order to draw a load of one long ton, in ordinary weather, over one mile of average road, the gradients on which do not exceed $2\frac{1}{2}$ per cent., on an average, is equivalent to 125 watts exerted for an hour. (Taking the daily run 70 miles and the weight of the car eight tons, it follows that the battery must be of such proportions that it can give out during the run as much energy as is equivalent to $70 \times 8 \times 125 = 70,000$ watts exerted for an hour. As this energy is not used during one hour, but distributed through say 14 hours, the battery will only need to be $\frac{1}{14}$ th of 70,000 watt-power, or 5,000 watt-power. If there are 125 cells, each having an E.M.F. of 2 volts, the E.M.F. of the battery will be 250 volts, and in order that it may develop the necessary 5,000 watts it must give a current of 20 amperes ($5,000 \div 250 = 20$). Ohm's law ($C = E \div R$) shows that if the current is 20 and the E.M.F. 250, the total resistance must be 12.5 ohms. Most of this resistance will be in the motor, which should be designed accordingly. It takes 746 watts to equal 1 h.p., so that 70,000 watts exerted for one hour is the same as $70,000 \div 746 = 93.8$ h.p. exerted for an hour. We may assume that the generator gives out 80 per cent. of the indicated h.p. of the engine that drives it. The engine would therefore be large enough to be able to exert 117.2 h.p. for one hour, if it did the charging all in one hour, since 80 per cent. of 117.2 is 93.8. If the charging of the battery lasts 20 hours instead of only one hour, the engine need be only $\frac{1}{20}$ th as large. That is, it will not need to exert more than 5.9 h.p.

The Sunbeam Lamp.—The *Western Mail*, in calling attention to the increasing value of the electric light for mining purposes, speaks very favourably of the Sunbeam lamp, first introduced by Messrs. Clarke, Chapman, Parsons, and Co., of Gateshead-on-Tyne, at the late Newcastle Exhibition, and it is being introduced into the South Wales district by Messrs. Walker and Olliver, of Cardiff. The *Mail* says:—"A very marked advance in the progress of electric lighting has recently been made by the introduction of the Sunbeam Incandescent Electric Lamp, which is now made to give from 200 candle-power to 1,500 candle-power, as required. In appearance the Sunbeam Lamp is simply a large form of the beautiful globes with their glowing carbon filament inside with which

we are all familiar, and with which the names of Swan in this country and Edison in America have been connected. Besides being larger, however, its carbon is also many times thicker than the delicate filament of the Edison-Swan lamp. As may easily be gathered, the Sunbeam lamp is intended to take the place of the arc lamp, and to provide what has hitherto been so difficult with arc lights, viz., lamps of varying power to suit varying conditions, without the necessity of adding complicated apparatus. It has also the further advantages that, while the light given is absolutely steady, the lamp itself requires no attention, except when required to be renewed, and that it may be worked upon any existing electric light circuit, so that it will now be practicable to have lights of any required candle power from 8 to 1,500 worked from one set of electric light plant, and each lamp, of whatever power, more easily controlled than even gas is at present. The Sunbeam lamp is particularly adapted for lighting quays, screens, colliery sidings, docks, ships' decks when loading, fitting shops, the halls and grounds of private mansions, hotels, &c., and many other large spaces, the perfect divisibility of the light making it available in places where hitherto neither the arc nor the small incandescent lamps were suitable. The Sunbeam lamps were employed in illuminating a large portion of the recent exhibition at Newcastle-upon-Tyne, and were awarded a silver medal, which was the only award obtained for incandescent lamps.

Atmospheric Electricity.—In a note presented to the Academy of Sciences of Naples, and entitled "Conditions which are necessary in order to obtain electrical manifestations by the spontaneous evaporation of water, and by the condensation of water, contained in the surrounding atmosphere, though an artificial lowering of the temperature," Prof. Palmieri, in spite of the negative results obtained by Knauer and others, insists upon the conclusion that a negative charge of electricity is produced by the evaporation and a positive charge by the condensation of water. He observes, however, that the evaporation and condensation must occur with a certain degree of rapidity in order to develop a perceptible electrical effect. Thus, for example, if an experiment be so arranged that a gram of water on a comparatively restricted surface is converted into vapour within 10 seconds, a very appreciable electrical effect is produced in an electroscope without the use of a condenser; whereas if the gram of water requires a minute for its conversion into vapour the production of negative electricity can be observed only by the use of the condenser. Further, if the same weight of water takes an hour to evaporate, it is no longer possible to observe any electrical effect. The fact is the same in the case of the positive electricity developed by the condensation of vapour in consequence of a reduction of temperature. In the daily electrometric observations, made either when the sky is clear or cloudy, the electrometer indication does not exceed 40deg.; it reaches 60deg. on the sudden production of dense fog, whilst on the occurrence of rain, even at a considerable distance from the locality of observation, the deflection is beyond the calibrated portion of the scale, and corresponds to some thousands of degrees. These high potentials are simultaneous with the production of rain, are maintained whilst it continues, and cease when the rain ceases. In reply to those who maintain that the slight electric currents produced by evaporation and condensation are insufficient to account for the tremendous effects of atmos-

pheric electricity, Prof. Palmieri points out that in the case of abundant rain, not accompanying storms, a fall of 1 millimetre of water per minute is of quite ordinary occurrence, i.e., 1 kilo. per sq. metre, or a million of kilos. per sq. kilometre, and that this would correspond to a condensation, on the platinum plate used in his observations, of 6 grams per minute, instead of half a gram, which is all that can be obtained by an artificial lowering of temperature.

Telegraphy in France. The statistics of the French Posts and Telegraph Department at the present time, as compared with those of a quarter of a century ago, show that very satisfactory progress has been, and is being, made. A comparison between the receipts accruing to the Treasury in 1860 and in 1886 amply proves this. In 1860 the posts and telegraphs brought into the Treasury in France and Algeria a gross total of 69,356,471f., with an expenditure of 51,319,932f., showing a net profit to the Treasury of 18,006,539f. In 1886 the receipts amounted to 172,915,928f., against an expenditure of 139,573,002f., representing an excess of receipts of 33,372,906f. The expenses of administration of the posts and telegraphs in 1886 are divided as follows:—Central administration, 2,062,940f.; working expenses in France 102,058,841f., and in Algeria 3,730,334f.; subventions in France 25,891,013f., in Algeria 879,999f.; reimbursements and restitutions, 4,949,890f. The general totals received for letters and telegrams in 1886 show that there has been an increase of 7,455,874f. over the Budget Estimates, as well as an increase of 2,448,297f. over the receipts for the year 1885; and for Algeria an increase of 274,853f. over the Budget Estimates, and an increase of 6,790f. over the receipts of 1885. These satisfactory results must be attributed to the constant development in the sending of letters and telegrams by the public, and to the more extended use of registered letters. The number of letters carried by the Post Office, including book parcels, &c., was 1,492,696,573. The total number of money orders issued was 21,499,029, representing a sum of 669,838,286f.; the total number of postal orders was 706,514, which reached a total of 6,873,823f. In Algeria 530,115 money orders were issued for 30,553,950f., and 5,958 postal orders for 56,095f. The total number of telegrams of every class sent by the department was 27,073,198. In 1860 the number of letters carried was 444,489,983, and the number of telegrams 924,993. It will be seen that marked progress has been accomplished in a quarter of a century, and that the postal circulation, and, more particularly, the telegraphic circulation have grown enormously during the last twenty-five years. The number of subscribers to the State telephones, which were 1,082 in 1885, has increased to 1,569 in 1886, an increase of 487 subscribers. The number of conversations held at the public telephonic cabinets, which were 94,441 in 1885, increased to 140,553 in 1886, an increase of 46,112. The Seine is largely responsible for the increase in the postal and telegraphic circulation of France. In 1886 the department which contains the capital, the centre of French intellectual, financial, and commercial activity, furnished to the Post Office receipts amounting to 42,471,436f., and to the telegraphic department 13,412,328f. The total product of the posts and telegraphs for the whole of France having been in 1886 169,446,874f., it will be seen that the department of the Seine has contributed no less than 55,883,764f., or nearly a third of the entire total. The French newspapers profess to regard these figures as being eminently satisfactory in every respect.

CONSTANT PRESSURE IN ELECTRIC TOWN MAINS.

II

In our last article on this subject we have considered the case of a single street with the generating station at one end, and have shown how by the employment of two feeders the total quantity of copper required for the underground conductor can be reduced to very little more than one-quarter of what would be required if the main were directly connected to the station. But so simple a case would hardly ever occur in practice, and, as a general rule, there will be not only one street alone, but a number of streets in which mains will have to be laid. If the streets radiate more or less from one centre, say the market place, and if it were possible to find in or near this centre room for the station, then each street would have to be served in the way shown in our last article by some feeders and a main, and the supply would be, so to speak, from the centre outwards. As a general rule, however, the land in the centre of a town is far too valuable to admit of its use as a site for the generating station, and this must, therefore, be placed at some distance from the best or most densely lighted portion of the town. It will also be only in exceptional cases that all the streets to be lighted radiate from one point. Generally speaking, there will be streets crossing each other in a more or less irregular manner, all of which require lighting. We thus get a network of mains with many crossing points, and it becomes difficult and often impossible to pre-determine for any given distribution of lights the direction and magnitude of the currents flowing through the different sections of the network. In the case of a single main running along a street, we have shown how copper could be saved by placing the lamps of higher voltage nearer, and those of lower voltage further, from the feeding centres. This arrangement was, however, only possible because we assumed the demand for current to be uniform throughout the length of the street, and knew, therefore, beforehand the direction of current in each part of the main. But even in the case of a single continuous main supplied by two or more feeders, the demand for current per yard run need not necessarily be a constant, and, therefore, the direction of current in any part may vary. To fix ideas, let our 400 yard main of the previous article be marked out into four sections, each 100 yards long, and call the ends A, E, and the three intermediate points B, C, and D. The feeding centres are at the points B and D, and when the full supply is on over the whole street, the current delivered at B will flow towards A on the one hand and towards C on the other hand, whilst that delivered at D will flow towards C on the one hand and towards E on the other hand. To adapt the lamps to the corresponding variations of pressure we would, therefore, place those of lowest voltage on the points A, C, E, and those of highest voltage on the points B and D. As long as the lighting varies uniformly throughout the street, this arrangement will be quite satisfactory, but see what happens if, for instance, all the houses between D and E take the full supply, and the rest of the street, with the exception of one house at A and another at C, takes no current at all. The lamps in these two houses are of 98.5 volts, and the permissible pressure must, for reasons already explained, not exceed 100 volts. Since hardly any pressure will be lost in the main between D and A (assuming that only a few lamps are alight in A and C), the pressure kept at D, in order to satisfy these two householders, must be 100 volts. On the other hand, the loss of pressure on the section D, E, where the full supply is on, amounts to 6 volts; and in order to satisfy the householder at E, we must keep 103 volts at D. We are thus forced either to overstrain the lamps at A and C by $4\frac{1}{2}$ volts, or supply $4\frac{1}{2}$ volts too little pressure to the lamps at E. Neither is admissible, and it will thus be seen that the expedient of using lamps of different voltage becomes impracticable as soon as the conditions of supply cease to be uniform. Another objection to the use of different voltage lamps is the complication which would thereby be introduced in the administration. The necessity to give every subscriber a different lamp would entail too much labour and lead to frequent mistakes.

The only plan for practically working the installation therefore to employ the same voltage lamps throughout and limit the rise and fall of pressure in the mains to $1\frac{1}{2}$ volts, as already explained. To satisfy the householder at E we would therefore keep 101.5 volts at the feeding centre D, and this would only overstrain the lamp A and C by $1\frac{1}{2}$ volts. The reasoning we have here applied to the case of a single main is obviously also applicable to that of a complete network. Accordingly as the demand for light shifts from one group of houses to another, so will the strength and direction of the current in each part of the network, and any arrangement of lamps which depends on the fall of pressure in one particular direction becomes impracticable. To make the installation a success we must therefore employ the same voltage lamps throughout: we must keep the pressure at the feeding centres constant at, say, 101.5 volts for 100 volt lamps, and we must lay down a network of mains of such a character that the pressure in any point and at any time, not fall below 98.5 volts. To make certain of this condition we imagine all the mains of the network about midway between one particular feeding centre and the surrounding feeding centres. The portion of the network thus isolated will then be supplied by one feeder, and the section of cables must be such that at the point where they have been cut the loss of pressure does not exceed 3 volts. By choosing a sufficient number of feeding centres, the portions of the network which we imagine isolated from the rest will be of very simple character in most cases consisting of a few mains radiating from one feeding centre, and the calculation of size is thus very easy. After connecting again the severed portions of the network, we are sure that the loss cannot be greater than 3 volts, but may be slightly less, owing to the tendency of the rest of the network to equalise the potential. The problem is therefore reduced to the following simple position. Given a certain number of feeders and maximum current in each, what provision must be made at the central station in order to keep the pressure at all feeding centres uniform?

It will be at once obvious that whatever arrangement of machinery and regulating appliances at the station is adopted, they must be such that the pressure on each feeder where it leaves the station can be independently regulated. The greater the current flowing out on any particular feeder, the higher must be the pressure on that feeder, the quantities being in the relation to each other as expressed by the formula

$$p = 101.5 + cr$$

where r is the resistance of the feeder, c the current, and p is the pressure, which must be kept at its original order that the pressure at the far end may be 101.5. But it is not sufficient to know the law according to which the pressure at the origin of each feeder must vary; we must also be able to ascertain at the station whether the pressure at each feeding centre is actually maintaining the standard of 101.5 volts, or, if departed from, in what direction a correction becomes necessary. The direct way to obtain the necessary indication is evidently to lay a separate pair of potential or indicating wires back from each feeding centre to the station, and in some Continental installations, provision is made for this purpose during the manufacture of the cable, one of the strands being insulated from the rest of the core and used as a testing wire after the cable is laid. Where no testing leads exist, a fairly accurate knowledge of the pressure at the far end can be obtained from observing the pressure and current at the station. To make the calculation it is, of course, necessary to know the resistance of the feeder, which is, to a certain extent, dependent upon its temperature, and therefore also upon the current. But for obvious reasons the variation in temperature can only be small, and will therefore not very much disturb the result. The pressure at the feeding centres can also be ascertained by means of a differentially wound meter at the station, as will be evident upon considering the formula

$$101.5 = p - cr$$

The high resistance coil on the voltmeter, if it were

would indicate the pressure p ; the low resistance which is in series with the feeder but acts in opposition to the pressure coil, would, if used alone, indicate the pressure p .

By correctly proportioning the two windings we can produce an instrument which indicates whether the relation between pressure and current, as shown by the formula, is being maintained, and any deviation of the needle from the mark corresponding to 101.5 volts can be observed, and the pressure on the feeder suitably regulated.

We have now narrowed down the general problem to that of suitably regulating the pressure at the origin of the feeder, and this might be done in either of the following ways:

1. Each feeder is supplied with current from its own dynamo, the speed or exciting power of which is regulated in accordance with the indications of the voltmeter at the feeder. All the dynamos are virtually coupled in series, not immediately at the station, but through their common connection to the network.

2. The dynamos are coupled in parallel at the station, and at 101.5 volts, delivering current to two main bars, from which the feeders branch off. Into each feeder is inserted a small dynamo to raise the potential of the outgoing and lower that of the incoming feeder in accordance with the external requirements.

3. The dynamos are coupled in parallel by two main bars at the station and work at a potential varying between 100 and 103 volts or a little over in the day time, and the pressure is regulated when the full supply is on in the network. All the feeders branch off from the main bars, the connection being made by means of rheostats, so that the pressure can be balanced against each other.

Of these three methods only the last has as yet been used in central station lighting. At first sight it appears as if this method were exceedingly uneconomical because entailing a considerable waste of energy in the rheostats. We shall, however, show that this is not so great as might be supposed. The other two methods are in theory perfect, entailing no waste of energy, but which in the feeders is unavoidable, but in practice there are serious objections to both. Let us first consider the method of installing a separate dynamo for each feeder. We have already shown that to save economy in copper it is necessary to use a large number of feeders, and therefore we would have to install a number of dynamos also, most of them of medium or small size. This not only makes the generating plant more expensive, but also complicates the working of it, and the liability of failure in the same proportion as the number of separate machines is increased. Another objection of the system is that either the machines must be of equal size, or else some of them must be too large to work at all times. But the greatest objection lies in the expense and difficulty of providing reserve machines. If a large number of such machines will have to be kept running, and very complicated arrangements will be required for effecting the substitution of a reserve machine when incapacitated whilst running. In fact, whilst a breakdown of one machine out of a number which are working in parallel would hardly be noticed at the station, a similar breakdown of a separate dynamo must perceptibly lower the pressure on that part of the network which is in the neighbourhood of its feeder. Another and scarcely less important objection is that the majority of the machines must be kept running all day. Although the machines may scarcely be doing any work in the daytime, yet we must keep them in motion so as to retain the standard pressure on all the feeders throughout the network.

Under the second plan, the objections to it are of a different nature, but of equal importance. It is true that in the parallel coupling of the main dynamos larger and a smaller number of them can be used, and a breakdown of one will only throw a little additional work on those left running without producing any sensible pressure outside, and that when running light the majority of main dynamos can be thrown off; but, on the other hand, the large number of small dynamos, for regulat-

ing the pressure on each feeder would introduce great complications and liability to failure. In this connection it must not be forgotten that we want twice as many small dynamos as there are pairs of feeders in other words, that an armature and commutator must be inserted in series with each branch leading to a feeder, whether this be an outgoing or returning feeder. To make this point clear, let us assume that we insert regulating dynamos only into the outgoing or positive feeders and see what would happen. Consider the case of two feeders, A and B, one passing the full current and losing 20 volts, and the other passing half current and losing 10 volts. The regulating dynamo on the positive branch of A would raise the potential from 101.5 to 121.5 volts, and that on the positive branch of B would raise it to 111.5 volts, assuming the potential of the negative main bar in the station to be zero. Now the loss on feeder A is equally divided between the outgoing and returning lead, and therefore at the feeding centre of A we would have 111.5 volts on the positive main of the network, and 10 volts on what we must call the negative main of the network, though its potential in reference to that of the earth is still positive. Where the feeder B joins the network we would similarly have 106.5 volts and 5 volts. But this is inadmissible. Not only the potential difference between the network mains at each feeding centre must be constant, but the absolute potential as well, for were it otherwise we would have strong currents flowing from one feeding centre to the other, and upsetting all our arrangements for equalising the pressure. To avoid this difficulty we must therefore raise the pressure in the positive branch of the feeder by exactly the same amount as we lower it in the negative branch. Thus, in our example, the positive branch of feeder A would at the station be raised to 121.5 volts, giving 101.5 volts at the feeding centre. The negative branch would be lowered to -10 volts, giving zero at the feeding centre and also at the negative main bar at the station. Similarly on feeder B one branch would be raised to 106.5 volts, and the other lowered to -5 volts. We require thus for each pair of feeders two dynamos, or at least a dynamo having an armature with two circuits and two commutators. Such an arrangement would evidently be too complicated for practical use, and hence there remains only the slightly wasteful but exceedingly simple method of balancing the feeders by artificial resistances for maintaining the pressure over the whole network constant. With this method we shall deal in our third article.

ELEMENTARY TESTING SUITABLE FOR ELECTRIC LIGHTING SYSTEMS.

BY THOMAS GRAY B.Sc., F.R.S.E.

[All rights reserved.]

(Continued from page 105.)

The tests which were given in the last part of this article as convenient for use during the construction of an isolated electric light installation are of course equally applicable to the more general case of a system of main and branch leads which are being laid down from a central station for the supply of electric light or electric power, or both. In laying down and extending central station systems each section should be tested and made perfect before it is joined to the mains, and it is important that the whole system should be so arranged that it can afterwards be easily broken up into manageable parts for testing purposes. In all cases where the branch mains, and the various sub-branches forming the network of leads, are supplied with both switches and automatic cut-outs, it is convenient to have the switch in one lead and the automatic cut out in the other. When this is the case any section can be easily isolated either for repairs or for testing without it being necessary to undo any permanent connection. It should be borne in mind that the tests already indicated are simply to be applied for guidance during construction, and are in no wise to be considered sufficient to insure absolute safety; the final tests must be much more searching, especially with reference to insulation from earth and between the different leads. The final

tests for insulation should, if possible, be made with an E.M.F. fully equal to, and it is better to be considerably higher than, the ordinary working E.M.F., and the tests of the material before it is sent to be installed should include a test for the rupturing E.M.F. This last, or rupturing force test, is of considerable importance for material which is to be used for alternate currents, especially where the maximum E.M.F. is high. Before proceeding to consider the final tests to which an installation should be subjected, and the tests which should be applied to the material, it will be convenient to consider somewhat fully the elementary principles of the different methods of testing which are in common use.

MEASUREMENT OF RESISTANCES.

1. *Wheatstone's Bridge Method*—This is perhaps the best known and most widely used method of comparing resistances which has yet been devised, and for a large class of measurements it is extremely convenient. The arrangement is indicated in Fig. 3. Suppose four resistances,

FIG. 3.

a, b, c, d , to be joined at the points, A, B, C, D; one pole of a battery, E, to be connected to, and the other pole through the key, K_1 , to B, so as to include the four resistances in its circuit; and the two points, C and D, to be connected through a key, K_2 , and the coil of the galvanometer, g . When the key, K_2 , is closed two currents flow through the quadrilateral between A and B, a and b forming one circuit, c and d another. It is clear that if the key, K_1 , is not closed, and hence no current flows through the galvanometer, the same current must flow through a , as flows through b , and likewise the same current must flow through d as flows through c . Now, by Ohm's Law, the current through any part of a circuit is equal to the electromotive force divided by the resistance between the ends of that part. Let then e_1, e_2, e_3, e_4 be the E.M.F.s between A and D, D and B, A and C, and C and B respectively, and we get the following simple equations:—

$$\text{Current through } a \text{ equal current through } b = \frac{e_1}{a} = \frac{e_2}{b}.$$

$$\text{Current through } c \text{ equal current through } d = \frac{e_3}{c} = \frac{e_4}{d}.$$

Now, if we further assume that when K_2 is closed no current flows through G, or that there is no E.M.F. between C and D, we have $e_1 = e_3$ and $e_2 = e_4$, and therefore

$$\frac{e_1}{a} = \frac{e_3}{c} = \frac{e}{a} \quad \text{and} \quad \frac{e_2}{b} = \frac{e_4}{d} = \frac{e}{b}$$

$$\text{but} \quad \frac{e_1}{a} = \frac{e_2}{b} \quad \text{and hence} \quad \frac{c}{a} = \frac{d}{b}.$$

We see, then, that if we have four resistances arranged as in the figure, and can adjust one or more of them until, when the key, K_2 , is closed, the closing of K_1 gives no deflection on the galvanometer, G , any one of the resistances can be calculated from the known value of one other, and

the known ratio of the remaining two. For example, let c be a coil of wire the resistance of which is required, and let d be a resistance which can be conveniently varied, while the ratio of a to b is known, then, when d has been so adjusted that with a current flowing through the circuit no deflection is produced in G by closing the key K_2 ,

$$c = d \frac{a}{b}.$$

Let, for example, $d = 500$ ohms and a and b both equal 10 ohms, then $c = 500 \frac{10}{10} = 500$ ohms. Again, if $d = 500$ as before, but $a = 10$ and $b = 1,000$ ohms, then $c = 500 \frac{10}{1,000} = 5$ ohms, and so on.

To facilitate the use of this method of measuring the resistance of conductors, boxes containing sets of coils adjusted with considerable accuracy to ohms and multiples, and submultiples of ohms, are made by most of the leading instrument makers. These vary very greatly in quality and correspondingly in cost. Examples of some of the different forms will be given below, and at the same time the main precautions which must be taken during the manufacture, and the methods of calibrating or adjusting them, will be described. These boxes generally contain, besides the sets of coils used as the adjustable resistance, two other sets of coils to be used in forming the two sides of the bridge indicated by a and b in the above examples. These two sets are usually, but not necessarily, adjusted to even numbers of ohms. They are designed merely to allow a convenient ratio to be given to the two constant resistances and to facilitate calculation the ratios chosen are almost always 1, 10, 100, . . . and 1, $\frac{1}{10}$, $\frac{1}{100}$, . . . This arrangement is very convenient, and is sufficient for almost all practical purposes, but it does not give the means of taking good advantage of all the sensibility which the method is capable of giving. The following rules should be as nearly as possible attended to while making the tests. Assuming c to be the resistance to be measured, g the resistance of the galvanometer and f that of the battery, then

Rule 1. The resistance of the side b opposite to c should be made as nearly as possible equal to the square root of the product of the resistances g and f , that is, b should be as nearly as possible equal to \sqrt{fg} , at the same time a should be as nearly as possible equal to

$$\sqrt{\frac{cf(f+g)}{c+f}}.$$

Rule 2. With a battery of any particular type it is always an advantage to add more cells until the resistance of the battery becomes equal to the resistance which is being measured.

Rule 3. With galvanometers of similar type that which has a resistance nearest to the resistance under test is the best.

Rule 4. The greatest sensibility is obtained when all the resistances, a, b, c, d, f, g , are equal.

The last rule must not be taken to mean that it is an advantage to use a high resistance galvanometer and a high resistance battery *per se* when testing high resistances, but should be read along with Rules 2 and 3, when its true meaning will be apparent.

There are practical difficulties which limit the application of these rules, and it may be instructive to consider some of them. In the first place the resistances in the sides a, b , of ordinary boxes of coils are generally 10, 100, 1000, &c., while the resistances in the box itself usually range from a minimum of $\frac{1}{10}$ of an ohm to a maximum of 10,000 ohms. Now consider a case, suppose the resistance of the galvanometer and the battery are each of them 10 ohms resistance, then the value of b is fixed at the $\sqrt{10 \times 10}$ or 10 ohms. Let a resistance of approximately 90 ohms be put

for c and we require to make $a = \sqrt{\frac{90 \times 10(10 + 10)}{100 + 10}} = 30$.

But a is to b as c is to d , and as a is thus three times b , the resistance to be put in the box is approximately one-third of c , or, in this case, 30 ohms. It will be observed that in this case d is equal to a , and this is always the case when $f = g$ and $b = \sqrt{fg}$. The point particularly to be noticed,

however, is that the resistance required in the box is less than that of the conductor under test and hence unless the box contains small resistances it becomes impossible to obtain an exact balance. The resistance required in the box in this method is always less than that under test when the latter is greater than the square root of the product of the battery and galvanometer resistances, and hence it is not always advisable to adhere rigidly to the arrangement for maximum sensibility. In all cases, however, where a resistance equal to \sqrt{b} can be got with sufficient accuracy in the box the method should be adhered to as closely as possible.

In the case given above, for example, where d was 30 ohms, a box containing resistances down to tenths would have given the resistance to one third per cent., while the amount of the deflection of the galvanometer to opposite sides when the nearest resistances, too high and too low, were inserted would give the means of estimating much more closely. It may be stated generally that, in accordance with the rules here given, when the resistance to be measured is high, a lower resistance than it is required in the box, and when the resistance to be measured is low, a higher resistance than it is required in the box, and in this respect the method is convenient as well as sensitive. There is, however, a somewhat serious objection to the use of unequal ratios at all in the two sides, arising out of the fact that unequal ratios are seldom so exact as equal ones, and besides very liable to be rendered inexact by unequal heating due to the passage of the testing current. There is still another chance of error in unequal ratios, and that is the probability of unequal change of resistance with change of temperature in the two coils, the wires being as a rule quite different in the two coils and hence the ratio is only accurate at one particular temperature. In well made resistance boxes the risks of error here referred to are minimised, and it is to be hoped means will soon be found of overcoming the difficulty altogether. This subject will be more fully discussed in its appropriate place.

With the regard to the general use of this method, it may be stated that it is capable of giving, when proper sets of standards of the ordinary pattern are provided, very accurate results for resistances of from 1 ohm upwards, but when the resistances are much lower than this some modification is generally advisable. Sir William Thomson about thirty years ago, made sets of coils so arranged that they could be used either in series or in parallel, and later he made boxes of "conductivities." Lately he has worked out a modification in some important details of his original plan of combined resistances and conductivities, and has named the arrangement, which is cylindrical in shape, a "mho-ohm drum." There is no doubt but that this combination system of conductances and resistances greatly lengthens the range of accurate measurement which can be obtained with one set of standards; but even then it is not advisable, on account of the unavoidable resistance at the terminal contacts, to measure resistances much below half an ohm in this way. Great care must be taken that the wires are clean at the points where they are pinched by the terminal screws, and also that the terminals themselves and the plugs and holes are perfectly clean. When proceeding to measure the resistance of any conductor, assuming the galvanometer and other connections made, first observe the direction of the deflection of the galvanometer either before the conductor is put in, and consequently c infinite, or after c is joined, and d is made either infinite or very high. This gives the means of telling when nearly enough, or too much, resistance has been inserted in the box, after which the adjustment can be readily made by observing the effect of successive small changes. As to the proper order of closing the circuit, it is usual to lay down the rule that the battery circuit must be closed first, and in a great many cases this is absolutely necessary. In some other cases it is not so convenient. In all cases where the conductor under test has considerable capacity, either electrostatic capacity, like an ordinary telegraph line or submarine cable, or electro-magnetic capacity due to self-induction, such, for example, as the capacity of the armature or field magnets of dynamos, the battery key K , must be closed first, and it must be kept closed for

a sufficient time to allow steady flow to be set up. It is not unusual to find that in inexperienced hands a dynamo is reported to have no definite resistance at all, while the whole fault lies in the battery circuit being closed for a variable and, in all cases, too short a time before the galvanometer key is closed. In cases where the coils of large magnets are being tested, the battery key may require to be closed for as much as 10 or 15 seconds, or more, before absolutely steady flow is established. When great accuracy is required, and the battery key must be closed first, it is well to use a reversing key in the battery circuit and test with both directions of current, so as to eliminate any thermo-electric effect in the circuit. The presence of thermo electric disturbance can always be detected by closing the galvanometer key, the battery key remaining open. There should be no deflection under these circumstances. When there is a deflection it may be allowed for by balancing to the same deflection, but it is better to use reverse currents and take the mean of the results. On circuits where there is practically no inductive impedance the galvanometer key may be closed first, and balance made to zero permanent deflection. Great care has, however, to be taken that there is no direct action of the current on the galvanometer causing a deflection when the battery key is closed, and also that the battery circuit and key are so well insulated that no current flows through the circuit when the battery key is open. The insulation of the battery circuit and key can be readily tested by varying the resistances in the bridge through a wide range and closing the galvanometer key when, if the insulation is satisfactory, no deflection, or, if there is some thermo-electric effect, no change of deflection should be observed.

(To be continued.)

PARIS UNIVERSAL EXHIBITION, 1889.

The Society of Telegraph Engineers has lost no time in bringing the question of the forthcoming exhibition to the notice of electrical engineers. We understand that a committee of its Council has been formed to consider the best methods by which British electrical science can be represented. A preliminary meeting of intending exhibitors will be held at the offices of the Society, 4, The Sanctuary, at 3 p.m. on Monday next, when, no doubt, the question of ways and means, as well as other important questions, will be settled. It is almost sufficient to prove that no effort will be spared to make this meeting a success, and to give full details of all that has been, is being, or is possibly to be done with regard to the electrical exhibits, when we say that Mr. Aylmer, the hon. sec. of the Society in France, will be present at the meeting. Those whose knowledge of the 1881 Exhibition is hearsay only, can have no conception of the unceasing energy displayed by Mr. Aylmer in connection with the English exhibitors, and we are glad to see him physically able to take an active part in the organisation of the 1889 exhibition. The commissioner to the electrical section of the exhibition is M. Berger, and those who know this gentleman will understand that every facility will be held out to exhibitors to enable them to make a successful display.

It may be stated here that even if there should be another English committee, for general exhibits, the doings of the electrical exhibitors will in no manner be under its control, so that the necessary arrangements for the latter can at once be made. The following information may be of interest to intending exhibitors:

Electrical instruments, machinery, and apparatus generally may be sent, either as ordinary exhibits, or as forming part of the arc light plant required for the illumination of the exhibition. No charge will be made for space, but the exhibitors will be called upon to pay their proportion of the general expenses of decoration, supervision, &c. Motive power, in the shape of belts, steam, water, or gas, will be supplied free of charge to exhibitors taking no part in the lighting. Exhibitors taking part in the lighting of the exhibition will be supplied with motive power at a moderate fixed sum, and in return will receive a share of the extra admission money paid by visitors entering during the

evening, in proportion to the amount of power rented by each exhibitor. The Director-General of the Executive Committee has given the assurance that the arrangements necessary for the convenience of British electrical exhibitors will be arranged entirely with the Society, which will act as their representative.

With regard to the total power required for lighting purposes, it is estimated at 3,000 h.p. The necessary motive power will be installed by a syndicate intrusted with the carrying out of the lighting. Out of the total power, M. Berger has reserved to the English section, for the use of intending contractors for electric lighting, 500 h.p., at a charge of £40 per 10 h.p., which is the minimum supplied for the whole time the Exhibition is open. The admission to the Exhibition during the day time will be 1fr., and during the evening, when the electric light is on, 2fr., the additional franc being equally divided between the general administration of the Exhibition and the electric lighting syndicate. The working expenses of the syndicate will be paid out of the £1 per horse power received from the lighting contractors, and out of the extra admission money, and if any profit be left it will be divided at the close of the Exhibition among the contractors who will have to bear the cost of their own installations and their maintenance.

Already a number of the best known firms have signified their intention of exhibiting, and as regards the 500 h.p. reserved for lighting, we should suggest immediate application, as here again firms have offered to take the whole. The power should be sufficient to permit every firm of repute to show the merits of their machines and lamps.

ON THE POSITION AND PROSPECTS OF ELECTRICITY AS APPLIED TO ENGINEERING.*

BY MR. WILLIAM GRIFFITH, OF EDINBURGH.

(Continued from page 115.)

Another interesting example of pumping is afforded by the recent introduction of electricity for this purpose into St. John's colliery, Normanton, where 39 gallons per minute are raised 530ft., equivalent to 6.3 h.p. of work done. An old girder-beam engine is utilised to drive the dynamo, and indicates 14.2 h.p. with full load. The efficiency throughout is therefore 44.4 per cent. The power lost in the different stages is as follows:

Engine and dynamo running		
light	1.7 h.p.	= 12.0 per cent.
Conductors	0.88	6.2
Motor and first shaft	2.8	19.7
Driving pump empty	2.0	14.1
Other losses	0.52	3.6
Total loss	7.9	55.6
Useful work	6.3	44.4
	14.2	100.0

It will be seen that only a small part of the loss takes place in the electrical plant, the greater part occurring in the pump, engine, and gear. The pump is driven by toothed wheels, which are worked from the motor by a cotton belt, in order to obviate transmitting the vibrations of the pump back to the motor. This plant is being extended to pump in addition 120 gallons per minute against a head of 900ft.

At Thallern colliery, on the Danube, where electricity has replaced steam for pumping, it has been found after several months work that a considerable saving in coal is effected, also that the temperature of the pit is reduced some 14deg. Fahr., steam having previously rendered the atmosphere of the mine unbearable.

In the mines of Blanzy, in France, a ventilating fan is driven from a generator at bank. The fan is 150 yards in, 2ft. in diameter by 11in. broad, and runs at 730 revolutions per minute. The temperature at the face has been

* A paper read before the Institution of Mechanical Engineers, February 2, 1888.

reduced 15deg., from 95deg. to 80deg. Fahr., since its introduction.

Shipyards. In shipyards and similar works electricity has already proved itself a suitable and economical means of transmitting power for riveting, drilling, &c. The electro-magnetic tools described in Mr. Rowan's paper at last year's Summer Meeting (*Proceedings* 1877, page 323) are being successfully employed in yards at Dumbarton. This system possesses the additional advantage that the tool can be firmly held to its work by magnetic attraction alone, without the use of bolts, so that no holes need be left for hand-riveting as is required with other machine riveters.

Transmission to great distances.—The transmission of power to great distances is not of such vast importance here as in the colonies, although even in the small sluggish rivers of this country there are large amounts of power running to waste. In many places where works have been erected for utilising water-power it has been at the sacrifice of convenience of situation, or of a ready and cheap means of receiving and despatching goods; whereas by means of electricity the same water power might have been transmitted to a locality more suitable for the works. For short distances it does not pay to transmit water power by electricity, owing, as previously mentioned, to the cost of dynamos; in such cases transmission by shafting or wire ropes is cheaper. But for long distances shafting is out of the question, wire ropes become more expensive, and electricity is cheapest. In Table I. is shown

TABLE I. First Cost of Plant per Horse power transmitted.

Total Power Transmitted	System of Transmission.	Distance of Transmission in Yards			
		110	1,100	11,000	22,000
H.P.	Electric	£ 76	£ 81	£ 142	£ 210
	Hydraulic	41	97	610	1,220
	Pneumatic ..	73	210	1,090	2,060
	Wire-Rope ..	6.5	61	760	1,220
100.	Electric	32	35	59	87
	Hydraulic ..	14	20	164	310
	Pneumatic ..	26	34	109	192
	Wire-Rope ..	1.1	8.4	81	162

the first cost of plant per horse-power transmitted through different distances by electricity, water, air, and wire rope. There is, of course, a limit beyond which it would not pay to transmit power, because with the distance the capital outlay increases, until the interest thereon outweighs the cost of the coal which would be consumed by a steam engine on the spot. Wire rope is, perhaps, cheaper for distances of less than one mile, although the disadvantages of having to lubricate pulleys and to provide substantial supports would in many cases compensate for the higher cost of electricity. The limit of distance to which it is economical to transmit water-power increases with the amount of power transmitted. From Table II., showing the cost of 1 h.p. per hour,* it appears that, when the power is generated by a fall of water, 5 h.p. can be transmitted 11,000 yards at the rate of 0.52 penny per h.p. per hour by electricity, while at the same rate also 100 h.p. can be transmitted 22,000 yards—that is, double the distance. The transmission of steam power over long distances is seen from the same table to be not economical, small power, say up to 10 h.p., may be transmitted as far as three miles, but larger powers not so far, because for larger power a local engine becomes more economical.

As an interesting instance of the transmission of power by electricity over long distances, that at the Phoenix Gold Mines in New Zealand may be referred to. The current is generated by two No. 8 Brush machines, each capable of giving 20,000 watts or 26 h.p., they are driven by Pelton water-wheels, with a head of 180 feet. The current is conveyed to the motor, about three miles distant, and back again, by a No. 8 B.W.G. copper wire (0.16-in. thick).

* This is a modification of a table given in Mr. Kapp's work on "Electric Transmission of Energy." The original table is based on the investigations of Herr Brincker and on the cost of power as determined by Prof. Grove.

TABLE II.—Cost of Horse-power transmitted per H.P.

Total Power Transmitted	System of Transmission.	POWER GENERATED BY A STEAM ENGINE				POWER GENERATED BY A FALL OF WATER.			
		Distance of Transmission in Yards.				Distance of Transmission in Yards.			
		110	1,100	11,000	22,000	110	1,100	11,000	22,000
H.P.		Pence.	Pence.	Pence.	Pence.	Pence.	Pence.	Pence.	Pence.
5	Electric	2.25	2.41	3.29	5.30	0.35	0.37	0.52	0.84
	Hydraulic	2.50	3.15	10.50	19.00	0.22	0.48	2.48	4.79
	Proprietary	2.70	3.30	9.53	16.70	0.24	0.48	2.40	4.45
	Wire Rope	1.13	1.88	10.00	22.70	0.11	0.22	2.22	4.86
100	Electric	1.79	1.91	4.03	4.03	0.20	0.23	0.32	0.50
	Hydraulic	1.62	1.78	4.15	6.24	0.16	0.19	0.72	1.14
	Proprietary	2.00	2.09	3.10	4.50	0.22	0.24	0.48	0.53
	Wire Rope	1.07	1.22	8.83	9.73	0.08	0.11	0.48	1.19

nearly six miles long, supported on telegraph poles. The power lost in the line is only 3 h.p. A Victoria motor is used, running at about 350 revolutions per minute, and the power is transmitted to the machinery by a belt.

Deprez succeeded in demonstrating practically that 52 h.p. could be transmitted over a distance of 35 miles, namely from Creil to Paris, through a copper cable equal in section to a wire of less than 0.2 in. diameter. But his machines were not efficient, the power required to drive the dynamo being 116 h.p., of which 41 per cent. was lost in the dynamo and motor, and 11 per cent. in the 70 miles of the outward and return wire. There is no reason, however, why much more efficient results should not have been obtained, as much as 18 per cent. of the total power was absorbed for maintaining the magnetism of the field of the dynamo, whereas in a well designed machine less than 5 per cent. should suffice.

Mr. C. E. H. Brown, of Oerlikon, has succeeded in transmitting by electricity 50 h.p. from water power at Kriestetten over a distance of 5 miles to Solothurn in Switzerland, with a commercial return of over 70 per cent. Two series dynamos and two series motors are arranged in the three wire system. Each of the three wires is in a motor, consisting of bare copper suspended on poles about 10 yards apart, with fluid insulators for ensuring good insulation. For a span of 130 yards across the River Aare, aluminium wire is used, which has the same conductivity as copper and a tensile strength of 30 tons per square inch. The current used is 15 amperes, and the potential difference at the terminals of each dynamo is 1,250 volts. The resistance of the line is 19 ohms, and the loss in it is a little over 3 h.p., or 6 per cent. of the total power. The loss in dynamos and motors is 24 per cent., being much less than in Deprez's machines where it was 41 per cent.

At Hatfield, on the Marquis of Salisbury's estate, the River Lea is utilised to generate electricity, which is transmitted to the house and over the estate for a variety of purposes. Two turbines are used, one to drive a 10 h.p. Siemens alternating current dynamo, for lighting the house; and the other to drive a 16 h.p. Brush machine, for arc lighting at night, and in the day for working the motors at the house and on the farm. Those at the house drive pumping and reaping machinery, and a 21 in. Blackman air propeller fixed in the roof for ventilating; on the farm the motors are used for elevating hay and corn sheaves to the tops of the stacks, for thrashing, for cutting rough grass with a chaff cutting machine for ensilage, in fields extending to a distance of two miles, for grinding corn, &c., to make fodder, and for other purposes. The motors have also been used for pile driving, for making cofferdams where necessary in the river, and also for dividing the river and clearing it of weeds. A Gramme motor, capable of raising 2,500 to 3,000 gallons per hour, pumps the town sewage into a tank at a height of 30 ft. for irrigation. The conductors are carried overhead on poles about the farm, and underground in wooden troughs to the house.

In favourable districts the supply of power to farmers by means of electricity is a subject well worthy the consideration of capitalists. If water power is not to be obtained as the prime mover, then steam power must be used as is now the custom, but in a more economical form than in a portable or traction engine. The expense of taking these

engines about the farm, both in coal and wages, must render them costly to the farmer in respect of the power actually used. An economical engine could be fixed, for generating an electric current to be transmitted through overhead conductors carried on poles along the roadside.

(To be continued.)

DRAKE AND GORHAM'S SWITCHBOARD.

Messrs. Drake and Gorham have designed the Standard Switchboard, herewith illustrated, for use in accumulator installations, though they can be modified to suit each installation.

Drake and Gorham's Standard Switchboard.

The switchboards are fitted throughout with Drake and Gorham's patent ring contact switches and steel yard measuring instruments, mounted on slate or polished and well seasoned teak boards.

The arrangement includes regulator switches for both "charging" and "discharging" accumulator circuits, also switches for lamp and dynamo circuits, provision being made for measuring the current in both circuits. For the convenience of contractors, all switchboards are supplied with the connections to the different switches permanently made at the back of the board; it is thus only necessary to solder the cables from the dynamo, accumulators, and lamps, into their respective sockets.

THE ELECTRICAL ENGINEER.

Published every Friday.
Price Threepence; Post Free, Threepence Halfpenny.

Editorial and Publishing Offices:
139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS 139-140 Salisbury Court Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. Special Terms for a series can be arranged on application.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at **THREE WORDS for ONE PENNY**, with a **MINIMUM** charge of **SIXPENCE**.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsvendor in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months.	6 months.	12 months.
United Kingdom	3s. 3d.	6s. 6d.	13s. 0d.
Within the Postal Union	4s. 4d.	8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 we gave a Portrait of E. GRAVES, Esq., President of the Society of Telegraph Engineers, and stated our intention of giving a series of Portraits of eminent Electricians of the century. In fulfilment of our promise we issued with our last number a Portrait of W. H. WOLLASTON, M.D., F.R.S., who was in his scientific prime at the beginning of the century. This will be followed by SIR HUMPHREY DAVY, F.R.S., whose fame as an electrician is still more prominent than that of WOLLASTON. Portraits of Past Presidents of the Society are in preparation, and we hope soon to have ready that of PROF. D. E. HUGHES, F.R.S.

SOME PLAIN SPEAKING.

Shareholders in tramway property are concerned in all that relates to the prosperity of such property, and at recent meetings they have been told again and again that chairmen and directors are always on the look-out for success in the way of electric traction. It is our province to frequently read the reports of meetings, and it is simply astonishing to find how a few promises, with a five per cent. dividend, satisfies the ordinary shareholders. We admit five per cent. to be a fair and a moderately safe return to look for, and probably the wisdom of the serpent teaches that a higher dividend brings keener competition. It is better at times in the interests of the directorate not to earn a greater dividend. Only by such reasoning as this can one understand why horse traction continues the ideal traction, so far as directors are concerned, for tramways. They are quite willing to take up electric or rope or any other system that can be proved to their satisfaction to be successful. That seems at first sight a fair position to take up, but on further consideration we are inclined to think it shows the worldly wisdom of the directors. Plainly, they do not want electricity, or cables or anything else to interfere with their present system; or if anything is to interfere they must somehow or other have a finger in the pie.

We do not wish to boast of what electricians can do or cannot do even in these early days of electrical engineering, but we do know that half-a-score of firms would successfully undertake the driving of ordinary tramcars electrically. There is nothing very startling in the task—certainly nothing to frighten the ordinary engineer. We are promised experiments upon the Metropolitan Railway—to propel trains—real trains electrically. Now that promise does somehow or other take our breath away. It is a big thing, as our cousins across the Atlantic would say; and although we do not despair of its being successful we certainly should not like to prophecy. Whatever be the result—if the promoters will only let their every arrangement be known, it will be fruitful of lessons. Possibly the general public—ourselves among the number—may have misunderstood the extent of these experiments. At any rate we will wish them success.

But, to return to tramcar traction. Why, if it is comparatively easy, has it not been adopted as extensively here as in America? History tells us that during the electric light boom promoters and patentees managed to thrive at the expense of the credulous. Our firm conviction is that gentlemen of this kind desire also to fatten upon what pickings they can get in introducing electric traction upon tramways. Farseeing individuals want to get a patent—with something in it to foist upon a confiding public—to the tune of tens of thousands. The directors of tramcars do not see their way to make a change unless they have a good reason for so doing—and the very best reason is £. s. d. It is not many years since iron rails were used upon all railways—then

steel rails were rolled, but we have yet to learn that the railway companies asked some one else to go to the expense of laying down such rails and proving their success. There were the rails; and the companies laid down a few, tested them, found them good laid down more still with success, till "steel" has replaced, or is fast replacing, iron. Where is the tramway company who will go to Elwell-Parker, Holroyd Smith, Magnus Volk, and give a definite order for a section of a tramway to be worked electrically, testing it fairly under their own directions? It is asking us to believe too much if directors go on month after month saying we are watching and waiting and hoping for this or that to happen. We do not think there is or can be anything very patentable about tramway design for the promoter to gain his ends; and the sooner this fact is brought home to the minds of directors the better. It is customary now to run to the Patent Office with every idea. The alteration in the pitch of a screw is sufficient to make a patent now-a-days, so is the grand idea of a round instead of a square brush to take off electricity. Really it seems as if Carlyle was right that the world is made up of wise men and fools, but mostly fools, or business would proceed more on the old-fashioned lines of going to a firm in the trade and stating what was wanted. *Designs ad libitum* would be forthcoming if the want was an electric tramway, and a competent engineer would have little difficulty in selecting a suitable one. As we say, when the desire is really to do the work the difficulties which now seem insurmountable will vanish like the mist before the face of the noonday sun; but while the idea is for somebody to make money by patents the obstacles will remain. At present we are told that the Electrical Engineer cannot devise a means to make a good yet safe contact, keep it free from dirt or water, and restrain the leakage to a minimum. It is graciously acknowledged that motors of, say, from two to ten horse-power can be made—that dynamos have arrived at a state of perfection leaving but a small margin for further improvement electrically or mechanically—yet we are told we cannot convey a current safely and economically over a distance of from two to six miles to and from the motor. Our opinion is that the time has come when the technical journals should firmly and respectfully combat these erroneous notions. Not only can we make the motors and dynamos, but we can design a complete system which would suffice for all the requirements of ordinary tramways. Just as we should not for a moment pretend to advocate an ordinary railway to the top of Snowdon, or Mont Blanc, or Mount Everest, so we do not advocate the use of electric traction indiscriminately. There are times and places where horses, cables, steam or other methods of traction are best. Our desire is to state, as emphatically as can be stated, that there exists no reason why fussy experiments should be made, or patents considered, or promotion money paid to introduce electric traction upon ordinary tram-

way lines. Dealing in "notions" is becoming almost as extensive in England as it is in America, and the good old plan of calling in an eminent engineer—a specialist in his own branch—to advise is not followed, at any rate so far as the electrical branches of engineering are concerned, because it is old-fashioned. We do not yet go to the men with "notions" to design our railway bridges or even our steam engines. We go to the men who have had a thorough training in the branch, and are acknowledged masters by their colleagues. The Institution of Civil Engineers has done much to remedy "quackery" in certain branches of engineering. Will the Institution of Electrical Engineers do as much for electrical engineering? If so, we may hope ere long to see promoters checkmated and their nostrums relegated to the backwoods, when work will be carried out in a proper manner, and progress will not be delayed because of a desire to gather in much money from a deluded public.

HIGHER CABLE RATES.

The whole tendency of the Anglo-American meeting, reported in another column, was to sing the tune of "sixpence will not pay." A fighting tariff has been tried and failed. The Commercial Company has held its own and will be the victor. This result might have been foreseen, but we must confess to having believed in the reality of the fight, and the determination once for all to put down competition across the Atlantic. As it is, the directors have pretended to fight

"With cautious step and prospect wary,"

while all the time intending to give in at a convenient season. From what we can see now, the arrangement between the rival companies might just as well have been made before the shareholders lost any of their dividends as after. The sixpenny tariff will not pay—that is the cry. It was made for a fighting tariff; but the shareholders will begin to ask where the benefit of the fight comes in? Was it not ever thus in the history of Atlantic telegraphy? Have not the directors blustered and sworn that they would fight to the death, but always in the end arranged to shake hands and contribute to a pool? The poor shareholder has had to pay the piper, though he could not call the tune. There are more cables in the Atlantic than are required. The business to be done is insufficient to fill the cables, or to pay a satisfactory dividend at this tariff, say the directors. It may be so, yet a closer inquiry into the question would show that, though not paying a satisfactory dividend, the low tariff ought to pay a better dividend than it has done. According to the chairman, the tariff was reduced from 2s. to 6d., and the messages have at the rate increased over one hundred and sixty per cent. The next question to be answered is the increase in cost to send this increase in messages. The increase should be comparatively small. Nothing is increased so far as the cable or electrical apparatus is concerned. The clerical staff, and the clerical staff only, should show increase of

expenditure. The odd ten or twelve per cent. will, we fancy, account for all necessary increase, leaving 150 per cent. to go to the ordinary fund. This is somewhat, though perhaps not exactly, the same as a tariff at 1s. 3d. on the old lines. Of course our line of argument may be altogether fallacious, but really from this reasoning it seems as if the dividend is not what it ought to be, that the fight is ended just when the public is putting the company into almost its old position by increase of patronage. It may pay directors to say that the public has benefited by this attempt at cheap telegraphy; so it has, but the directors care as much for the public as we do for the gnomes and fairies of children's tales. The raising of the tariff will not recoup the shareholders their loss. If, on the other hand, the fight had been real and a victory won, the shareholders would have been fully recompensed for the loss sustained. The Commercial Company would not in so short a time have put itself upon a level footing with the older companies as it has done, had they been contented with accepting the 1s. 8d. rate in lieu of the 2s. rate. Now the probability is that the whole of the Atlantic cables will form a pool and share *pro rata* according to capital. The 'cute Yankee has indeed been fortunate this time. Anglos will perhaps rise a point or two, and those who have loaded heavily during the time of the so-called fight will rejoice at the turn affairs have taken. The puzzle is to know who are the fortunate ones.

NOTES ON THE ELECTRIC LIGHT IN SOME CONTINENTAL CITIES.

BY R. H. COLLINS, OF THE LIVERPOOL ELECTRIC SUPPLY CO.

Paris.—In the neighbourhood of the Louvre, and in the Place de la Concorde, Jablochkoff electric lamps are used, suspended from pillars, some 20ft., others 60ft. high. Of the many installations in Paris that of the new theatre, the *Nouvel Opera*, forms a great attraction, the building being most sumptuously fitted up in every respect.

Lucerne. The *Schweizerhof Hotel*, of large dimensions, near the quay side, is fitted throughout with electric light, both arc and incandescent lamps being employed. The fittings used are substantial in appearance and tasteful in design. Arc lamps are placed outside to illuminate the gardens in front, and also afford light to a good orchestral band which possesses a stand near the hotel. The current for this hotel and several other buildings is supplied from the works of Gebrüder, Troller, and Co., at Dorenburg. At Lucerne there is a small private generating station which supplies a hotel near the lake with current for 250 incandescent lamps. The dynamo employed here is one manufactured by R. Allott and Co., Suisse "Helvetia" type, and gives 150 amperes and 120 volts at 850 revolutions. It is fixed on a stone bed with sliding gear for tightening, and is driven by a semi-portable engine and boiler made by Gebrüder Sulzer, Winterthur. One man has the entire charge of the plant, and appears to keep everything in proper working order. There is a voltmeter and ammeter made by R. Allott and Co., mounted on a board on the wall, for testing.

Como. The electric light has recently been introduced for the first time in this beautifully-situated city. This preliminary installation consists of five arc lamps, fixed on poles 30ft. high, in the *Giardino Publico*, or public gardens, four of them being placed outside a "Podiglione Excelsior,"

or cafe, and the fifth lamp being situated near the main road fifty yards off. Close to the main road the engine shed is situated. The dynamo used here is of the Burgin type, manufactured by Altorf Bros., of Bâle, and is fixed on a stone bed 1ft. 6in. high. A semi-portable engine and boiler (local make) provides the motive power. There is an ammeter (indicating eight amperes when lamps are at work) and a small frame with resistance coils fixed on one side of the engine room. One man is employed to look after the plant, and the light is remarkably steady. Outside this cafe numerous small round tables are placed, and a temporary stage in the open air is also provided for concerts, &c., the electric light shedding its radiance over all. Doubtless further additions will shortly be made in Como, now that the light has obtained its preliminary footing.

Milan. Electric lighting here is general throughout the greater portion of the City, both as regards arc as well as incandescent lighting. The mains are all underground. In the principal buildings, fittings of the most elaborate description are used, while in the less important houses plain iron pipe fittings are fixed. The large central generating station of the Edison Company which supplies the current, is situated in the basement of an oblong building about 120ft. long by 35ft. broad, in a narrow street not far from the cathedral. Eight old type Edison machines about 7ft. and 6ft. high, giving 800 amperes and 110 volts at 350 revolutions, and driven direct by engines of Arrington and Sims type, are placed in a row down nearly the whole length of the basement, with an interval of a few feet between each. On one side there are four Thomson-Houston dynamo machines used for the arc lighting, the incandescent lamps being supplied with current from the Edison machines. The mains leave the premises from both ends of the building. Some of the arc lamps in the streets are arranged on iron pillars about 30ft. high, whilst others are hung from an iron chain stretched across the street. Near one end of the chain there is a short iron rod screwed into an iron ring, which tightens or loosens the chain as desired. In the justly renowned *marble cathedral* the electric light is used, but the usual candles still predominate at the High Altar. At the *Scala Theatre* upwards of 1,000 electric lamps are employed in the various rooms and body of the building. One massive gilt metal electrolier fixed in the centre of the theatre contains 400 lamps. In the principal promenade room there are three electroliers with 108 lamps in each, and other rooms possess fittings with lamps varying in number, viz., 32, 20, and 7 each. There are six tiers of galleries to this theatre, and looking from the pit, 300 lamps can be seen distributed in 60 brackets of 5 lamps each, round the sides 10 brackets for each tier of gallery. The switchboard arrangements are on the right hand side of the orchestra. There are other controlling switches situated in the basement. The wires used throughout the building are covered with an insulation of asbestos.

Turin. At Turin there are three small generating stations for electric light, viz., The *Via Librario*, *Piazza Castello*, and the *Istituto Tecnico*. Over 500 h.p., is used in Turin for electric lighting. The ground is of a dry gravelly nature and particularly suitable for underground mains, which are placed about 2ft. deep and 3ft. from the sides of the streets. The Edison system of mains is used in several parts of the city. Near and in the railway station, Siemens arc lamps are employed, and also at the *Piazza Milano* and *Piazza Castello*. Four iron pillars about 50ft. high are erected in each of these squares. They are substantially constructed, and neat in design. At the foot of each lamp there is a testing box covered with an iron plate. In the neighbouring arcades "Cento" incandescent lamps, protected by well glasses, are attached to plain metal pipe pendants, the lamps being about 9ft. above the ground. In the *Via Garibaldi*, 50 Thomson-Houston lamps are employed to illuminate the street, and are suspended from curved brackets fixed in the walls about 20ft. above the ground level. The bottom half of the lamp globes is frosted to prevent a dazzling effect. Other streets in the neighbourhood are lighted with from 20 to 30 lamps placed at distances of about 30 yards apart. The electric light is gradually gaining ground here.

Geneva.—The electric light was temporarily employed here during the occasion of the festival in August last, Thomson Houston lamps being used in the Rue du Mont Blanc and neighbourhood. It is proposed by a local company to put down a central station for supplying electric light generally, as soon as matters have been arranged with the authorities. The swift-flowing waters of the Rhone as they leave Geneva will form an excellent means of providing cheap motive power, as already 1,200 h.p. is being developed by five turbines for other purposes, and the "Batiment des Turbines" is now being extended, which extension it is proposed to adopt for electric lighting at an early date.

AN ELECTRIC NIGHT LIGHT.

The accompanying illustration shows a little arrangement of Messrs. Woodhouse and Rawson, which is at once elegant and useful. It is often convenient at night to instantly obtain a light, and yet there are many objections to always have a light burning. The "tallow" men have long had it all their own way in providing night lights, but now electricity promises to supply something better. A small 1 candle-power 1 volt lamp is fitted near the bed's head,

the push to make contact being well within reach. With the lamp, if there is no dynamo or secondary battery handy, it is usual to supply a battery of four Leclanche cells. The whole is cheap, handy, and effective.

CORRESPONDENCE.

ELECTRIC LIGHTING.

[The following letter appeared in *The Times* of Friday last, in continuation of the correspondence commenced by Major Flood Page, whose letter appeared also in our last issue. *Ed. E. E.*]

SIR, The public are under a great obligation to your well known correspondent, Major Flood Page, whose letter you printed yesterday, for his very clear and powerful advocacy of the strong claims of electric lighting on the immediate attention of Parliament. As he has referred to my Bill, which passed the House of Lords last year, and expresses in very kind terms the hope that I may re-introduce it this year, I beg to say that it is my firm intention to lay it again on the table of the House of Lords so soon as Parliament re-assembles. At the same time, I entirely concur with Major Flood Page in hoping that Government may see fit to deal with the question this Session, and enable me to withdraw my Bill and give my hearty support to their measure.

The only point on which a difference of opinion practically exists in Parliament is on Clause 27 of the Act of 1882, which governs the compulsory purchase of electric lighting undertakings by local authorities after 42 years (42 years being now generally conceded in place of the original 21 years).

The Board of Trade oppose any valuation of the "goodwill" of the business. We, on the other hand, feel that nothing short of a fair valuation of that asset will insure the public being well served during, say, the last ten years of the life of a provisional order. If the valuation for compulsory purchase by a local authority at the expiry of 42 years is made on narrow principles, such as mere break-up value, without a due regard to maintaining the thorough efficiency of the plant, we hold that there is a serious danger of electric lighting undertakings being allowed to run down towards the expiry of their term, to the detriment of the public.

It is, however, possible that sufficient, fair, and reasonable profits may be derived from the business during the period of 12 years to encourage the flow of capital into electric lighting undertakings which 21 years have failed to do, but we think it politic to give an electric lighting undertaking every encouragement to maintain its plant in the highest state of efficiency up to the expiry of its life of 42 years, and that for this purpose it is necessary "goodwill" should be considered as an asset for valuation in the event of compulsory purchase by the local authority.

If, on the other hand, it can be legally held and maintained that the valuation "as a going concern" sufficiently covers this point and affords sufficient protection to the public, I for one would be glad to drop the obnoxious word "goodwill." Yours, &c.,

33, Chesham-place, S.W., Feb. 1.

THURLOW

COPPER IN DYNAMOS.

Our contemporary, *l'Electicien*, observes that a few years ago these machines were constructed quite empirically. The constructor made a machine, experimented with it, and by means of the results obtained he arrived at data for a type of machine of given power. But since then things have much altered, and it has frequently occurred that the same power has been obtained when the weight of copper in the field-magnets or in the armature has been very much reduced. In relation to this question, M. Wilhelm Penkert, of Vienna, has compiled the following table, published by our contemporary *Zeitschrift für Elektrotechnik*.

Machine.	No. of revolutions per min.	Diff. of potential in volts.	Electrical power in watts.	Total weight of copper in kilos.	Grams of copper per useful watt.
Crompton	300	110	72,000	637.1	8.85
Crompton	700	110	54,000	475.7	8.77
Ganz and Co. (V.P.)	670	105	50,400	240.0	4.76
Gooden and Trotter	765	56	16,000	104.6	6.54
Gooden and Trotter	1,070	77	22,000	104.7	4.67
Brush	400	80	300,000	3,000.0	10.0
Ganz and Co. (ring machine) with six poles	1,000	1,500	52,000	82.0	1.56
Crompton Type No. 30	300	110	26,300	393.0	15.5
Mather and Platt	1,000	100	22,000	144.0	6.4
Lalameyer, G. III	1,250	65	3,900	50.3	12.89
H. Page	840	88	6,500	58.3	8.96
Holmann	750	100	100,000	556.0	5.5
J. Einstein and Co.	1,100	100	4,500	35.0	7.7
Edison-Hopkinson	800	100	33,000	118.0	3.57
C. E. L. Brown	1,000	65	10,400	45.0	4.32
C. E. L. Brown	1,000	55	6,600	21.6	3.3
Brush	1,000	100	390,000	2,833.0	7.45
Edwell Parker	1,000	110	50,600	454.0	9.1
E. Fein (interior pole machine)	520	110	15,000	88.4	5.83

It will be observed that machines made about three years ago gave 1 watt for every 30 or 35 grams of copper, whereas the machines of Ganz and Co., at the present day, gave 1 watt for every 1.6 grams of copper.

Meteorological Society.—At the ordinary meeting of the society, to be held on Wednesday next, the following papers will be read: "Electrical and Meteorological Observations on the Peak of Teneriffe," by the Hon. Ralph Abercromby, F.R.Met.Soc.; "Rainfall of South Africa, 1842-1886," by W. B. Tripp, M.Inst.C.E., F.R.Met.Soc.; "Some Methods of Cloud Measurements," by Nils Ekholm.

ON ALTERNATE-CURRENT TRANSFORMERS, WITH SPECIAL REFERENCE TO THE BEST PROPORTION BETWEEN IRON AND COPPER.*

BY HERBERT KAPP, MEMBER

The principle on which all induction coils, and therefore all the different forms of alternate-current transformers, depend is that of a magnetic circuit interlacing with an electric circuit. In its simplest form this relation can be represented by two rings threaded through each other (Fig. 1), one representing the

FIG. 1.

electric circuit (coloured red in the diagram to indicate the copper wire), and the other the magnetic circuit (coloured blue in the diagram to indicate the iron core). Modern transformers have all a closed core, so as to compel, as far as possible, all the lines of the magnetic circuit to pass through the electric circuit,

which consists of a primary and secondary coil, but they differ from each other in the particular manner in which the circuits are arranged, with a view to attain the following objects: Reduction of the length of the two circuits, reduction of the weight of materials employed, ventilation, facility of manufacture and repair, efficiency of insulation, and reduction of cost of manufacture. Omitting for the present those considerations which more nearly concern the practical manufacture, we may divide transformers broadly into two classes—one in which the copper coils are spread over the surface of the iron core, enveloping the latter more or less completely; and the other in which the core is spread over the surface of the copper coils, forming a shell over the winding. I propose to call the former "core transformers," and the latter, "shell transformers." A familiar example of the first class is the armature of an ordinary Gramme dynamo, whilst the particular type of transformer introduced by Mr. Zepernowski may serve to illustrate the second class. They are represented in the wall diagrams (Fig. 2 and 3), the copper being coloured red and the iron blue. It is evident without mathematical investigation that, whatever may be the proportion between the external and internal diameter of the ring, the electric circuit must be shorter than the magnetic circuit in the Gramme ring or core transformer, whilst the opposite must be the case in the Zepernowski ring or shell transformer. When, a few years ago, this type was introduced, it was, on account of its short magnetic circuit, generally believed to be an immense improvement upon the Gramme ring; and I have heard it stated that with the Zepernowski outside core absolute perfection has been reached, since "every inch of copper wire contributes to

produce electromotive force." I propose presently to lay before you a short investigation into the relative merits of the Gramme and Zepernowski rings, and also into the best proportion of copper to iron in either, but before entering into this subject I would submit a few theoretical considerations, so as to obtain a basis for this investigation.

Since the electromotive force developed in the secondary circuit is proportional to the coefficient of mutual induction between that and the primary circuit, and since self-induction tends to produce lag and so reduce the output of the apparatus, it is obviously advantageous, both for efficiency and output, to so arrange the coils that their coefficient of mutual induction should be a maximum for the given coefficients of self induction in the primary and secondary circuit. According to a well known law, the maximum value which the coefficient of mutual induction can have is equal to the square root of the product of the two coefficients of self induction, and the necessary and sufficient condition for obtaining this maximum is that the same number of magnetic lines of force should pass through both circuits. In other words, the whole of the flow of force should take place within the core, and no free poles should be formed. This condition can easily be fulfilled by a suitable arrangement of the two circuits in close proximity, and, as a matter of fact, is fulfilled in all modern transformers. We shall therefore assume that the same flow (F) of magnetic lines of force passes through both circuits, and that the electromotive forces produced in the two circuits bear to each other the same proportion as their respective number of turns. We shall further assume that the electromotive force impressed on the terminals of the primary coil, or the current sent through it, is a simple sine function of the time in other words, that the electromotive force developed in the armature of the dynamo is such a function. Whether the latter

condition is generally fulfilled by modern machines I am unable to say; but I believe that the presence of a transformer in the circuit has the tendency to smooth down any deviations from a true sine curve should they occur in the armature, and, further, that a curve of E.M.F., of whatever shape, produced by a machine will, after filtering through two or three transformers, come out as a true sine curve. It would be of value if someone having the necessary mathematical attainments would investigate this point; but for our present purpose it is sufficient to assume that the electromotive force produced by the machine follows with fair approximation a simple sine function, and that the deviations are unimportant. This assumption has up to the present been made by all who have investigated the subject of transformers.

Let in the following:

- n represent the number of complete cycles performed per second;
- F flow of force in C.G.S. lines;
- B maximum inductions (crest of wave);
- τ number of turns in the coils, the indices 1 and 2 being used to distinguish the primary from the secondary coil;
- E maximum electro-motive forces (crest of wave) in volts, the indices 1 and 2 being used to distinguish the primary from the secondary coil;
- $e = \frac{1}{\sqrt{2}} E$.. average electro-motive forces;
- I maximum currents;
- $i = \frac{1}{\sqrt{2}} I$.. average currents;
- L length of the magnetic circuit in centimetres;

* Paper read at the Society of Telegraph-Engineers and Electricians, February 9th, 1883.

a represent the area of core available for the flow of lines in square centimetres;

$R = \frac{l}{\mu}$.. magnetic resistance of the core;

μ .. its permeability;

r .. the electric resistances;

then we have the following well-known relations:—

$$R = \frac{l}{\mu}, \quad F = \frac{4\pi r I 10^{-9}}{R}; \quad E = 2\pi n F 10^{-9}; \quad \frac{E_1}{E_2} = \frac{n_1}{n_2}$$

Calling e_{11} and e_{12} the average electromotive forces at the primary and secondary terminals respectively,

$$e_{11} = e_1 + i_1 r_1; \quad e_{12} = e_2 - i_2 r_2$$

When a transformer is at work we have the following phenomena:—

1. A wave of impressed primary electromotive force
2. A wave of counter electromotive force in the primary coil, but not exactly coinciding with the impressed.
3. A wave of primary current not coinciding with either
4. A wave of magnetisation lagging behind the primary current wave by something less than a quarter period.
5. A wave of electromotive force in the secondary coil lagging behind the magnetisation wave by a quarter period.
6. A wave of secondary current, coinciding with the former (5) in period if the external circuit contain no self-induction—a condition approximately fulfilled where the current is only used for lighting glow lamps.

The problem now is to find what relations exist between these different waves as regards their relative positions and magnitudes. At first sight it may seem that this would prove a very difficult problem, and if an algebraic solution be attempted it is, in fact, if not very difficult, at least enormously complicated; but it is easy to treat the matter geometrically in a very simple way. As this method has already been published some time ago, it will not be necessary to demonstrate it, and I shall limit myself to a brief description, pointing out a modification of the original method by which the energy dissipated in magnetising the core can be taken into account. It will be seen from the above equations that F and E are proportional. Consequently, if we know what E.M.F. is to be put on the primary terminals of a given transformer, we also know with very close approximation what the induction and total flow of lines will be. If it were not for the slight disturbing influence of the resistance of the primary coil, we would know these data exactly. But the loss of E.M.F. by resistance can, for obvious reasons, only be trifling, and will in most cases be settled beforehand. We can therefore determine F with perfect accuracy, and from the constructive data of the core also the exciting power (τI) which will produce this flow. It will be shown presently that it is inexpedient and uneconomical to work transformers with a high induction, and we may therefore regard the permeability to be constant for all points in the cycle. In this case I and F must at all times be proportional. Let, in Fig. 4, the circle represent the effective exciting power which we assume to coincide with the magnetisation, so that the projection on the vertical of the radius OP as it revolves (clockwise) round O represents the effective exciting power in ampere turns, and, to a different scale, also the flow of force at any instant. The line representing the current in the secondary must evidently lag behind OP by a quarter cycle, and can be calculated from the formula for E_2 and from the resistance of this circuit. This gives us OL_2 the maximum exciting power due to the secondary coil alone. By erecting a vertical on OP in P , and making $PL_1 = OL_2$, we find the line OL_1 , which represents in position and magnitude the maximum exciting power due to the primary coil alone. This gives us also the primary current, and we can now determine the loss of electromotive force due to the resistance of the primary coil. Let OR_1 represent this in direction and magnitude. The counter electromotive force in the primary must evidently be in advance by a quarter period over the magnetisation, that is to say, it must be represented by a certain length on the line OY . Its amount can be calculated from the formula for E_1 . Let OE_1 represent it to the same scale as was used for OR_1 ; then the parallelogram $OR_1E_1E_2$ gives us at once the point E_1 and line OE_1 , which represents in position and magnitude the maximum electromotive force impressed on the terminals of the primary coil, and a is the angle of lag of current behind impressed E.M.F. The work done on the primary coil is found by the well-known formula

$$W_1 = \frac{I_1 E_1}{2} \cos a;$$

$$W_1 = I_1 e \cos \frac{a}{2}$$

That is to say, the true work is equal to the product of the apparent work, as measured by a dynamometer and voltmeter, and the cosine of the angle of lag. If the apparatus were supplied

with current at a constant and undirected E.M.F. the apparent and the true work would be equal, and the ratio $\frac{1}{\cos a}$ indicates

how much larger must be the capacity of an alternate-current plant to do the same true work as a continuous-current plant. I propose, therefore, to call $\cos a$ the "plant efficiency" of the transformer.

It was stated above that transformers should be worked at a comparatively low induction. This might seem at first sight a retrograde step, since with dynamo-machines considerable gain in efficiency and output has resulted from adopting an induction up to 20,000 and more; but by reference to Fig. 4 one of the reasons why a low induction is preferable will be at once apparent. Suppose that the line OP represents the limit to which the induction may be pushed without diminishing the permeability; then, if the same transformer be worked at double the electromotive force, we would require an exciting power not only twice, but many times, as great as previously. This would bring the point P considerably to the left without increasing the length of the line PL_1 . It would also increase the length of the line OL_1 , that is, the primary current, and therefore the heat generated in the primary coil, whilst the angle of lag would become greater and the plant efficiency smaller. Similar results would follow from an increase in the magnetic resistance of the core, or from the omission of a core altogether. An early type of transformer made by Messrs. Gaulard and Gibbs had no iron core, and therefore no well-defined magnetic circuit, but as the primary spirals alternated with the secondary spirals our previous assumption regarding the coefficient of mutual induction remains valid, and the above formulae and graphic method could be applied to this apparatus if we knew what value to assume for the resistance of the magnetic field. This, however, we do not know; but the case is of no importance at present, as transformers without iron cores have become obsolete. I only mention this early apparatus because the experimental investigations of Dr. Hopkinson and Prof. Ferraris* have proved that there is a considerable difference between the apparent and the true work—that is to say, the point P must have been a considerable distance to the left, making the plant efficiency small. In modern transformers the point P lies so close to O that the plant efficiency may reach as high as 99 per cent., so that the difference between real and apparent work supplied to the apparatus when giving full output becomes trifling, and for a practical determination of efficiency the readings of measuring instruments on the primary and secondary circuit may be used, with only such corrections as may be applied from the diagram.

A high plant efficiency is, however, not the only reason why transformers should be worked at a low induction. A far more important reason is the heating which takes place in the iron of the core if this be carried rapidly through cycles of intense magnetisation. This heating is not due to eddy currents (although these currents in a badly designed core would produce the same effect), but seems to be the result of what may be termed dissipation of energy by molecular friction or hysteresis. The energy dissipated per cycle per cubic centimetre increases in more than simple ratio with the induction, and it seems also to increase as the periodic time decreases. As yet very few experiments have been made to determine the hysteresis for different samples of iron, the most important data published being those given by Prof. Ewing and Dr. Hopkinson in the *Philosophical Transactions*, Part II., 1885. Prof. Ewing distinguishes between static hysteresis (slow period) and viscous hysteresis (quick period), but the experimental data refer only to the former. According to Dr. Hopkinson, the energy required to carry one cubic centimetre of annealed wrought iron through a complete cycle of induction equal to 18,251 lines is 13,356 ergs, and for hardened tungsten steel with an induction of 14,480 lines the energy reaches 216,864 ergs. Prof. Ewing found that with very soft annealed wrought iron and $B = 13,190$ the energy dissipated by hysteresis was 9,300 ergs. He also tested annealed iron wire by carrying it through lower cycles, and, as the results are of very great importance in the construction of transformers, they are given herewith:

Induction.	Energy.	Induction	Energy
1,974	410	10,590	5,560
3,830	1,160	11,480	6,160
5,980	2,190	11,960	6,590
7,180	2,940	13,700	8,690
8,790	3,990	15,560	10,040

These figures refer to static hysteresis. As regards viscous hysteresis, no experiments have been made, but in the case of $B = 8,500$ and $n = 80$ Prof. Ewing estimates the energy dissipated per cycle at 5,000 ergs, or 32 per cent. above that of static hysteresis. When applying the figures of the table to transformers, it may, therefore (until further experiments have been made), be advisable to add from 30 to 40 per cent. to the energy there given. Thus, if an induction of 18,000 be adopted,

* "Ricerche Teoriche e Sperimentali sul Generatore Secondario" Gaulard e Gibbs, by Galileo Ferraris. Turin, 1885.

the energy dissipated would amount to 18,000 ergs per cubic centimetre per cycle, and with 80 cycles per second this corresponds to 144 watt per cubic centimetre of core. It would evidently be extremely difficult, if not altogether impossible, to provide cooling surface enough for this rapid generation of heat, and hence it is necessary to work at a lower induction, the exact amount to be determined for each transformer by the cooling surface of the core and coils, and by the heat generated in the coils themselves. So far, then, theory points to the necessity of low induction. As regards practice, I believe the makers of transformers have already found out that it does not pay to press the iron magnetically too hard. My own experience was at least in this direction. In the first transformer which I designed jointly with Mr W. H. Snell, and which is on the table, we worked at an induction of 20,000, and there were produced two very undesirable results. In the first place, the core heated to such a degree that continuous work was out of the question; and, in the second place, the apparatus emitted a most unmusical sound, and it was evident that on this account alone it was not fit for practical use. The sound may have been partly due to the employment of wood for the framework, but we believed that the high induction was principally the cause, and by dropping the E.M.F. so as to get an induction of 15,000 we found that these evils were lessened. We then constructed another transformer, in which the induc-

tion was reduced to 10,000. This transformer is also on the table. In it the sound was suppressed, but the temperature still rose by about 30deg C. when continuously at work. We have therefore, in a later design, adopted a still lower induction. Although it is possible to reduce in this manner the amount of energy dissipated in the core, this waste cannot be entirely prevented, and must therefore be taken into account when determining by the aid of the diagram the working conditions of the apparatus. For this purpose it would, strictly speaking, be necessary to know, in addition to the total energy dissipated per complete cycle, also the rate of dissipation at each point of the cycle—a knowledge which we do not possess. It seems, however, reasonable to assume that the rate of dissipation of energy by hysteresis follows the same law at the rate of dissipation of energy due to eddy currents: that is to say, that it is proportional to the rate of change of induction. When the induction passes through zero, the rate at which heat is generated would be a maximum, and this would gradually diminish to zero as the induction approaches its positive or negative maximum. On this assumption we can imagine eddy currents substituted for hysteresis, and in an iron core perfectly devoid of the latter

property—that is, infinitely soft—the same amount of heating could be produced by imperfect subdivision, or, better still, by subdividing it perfectly, but wrapping round it a closed conductor of such a resistance that the heat generated in this conductor equals that dissipated by hysteresis in ordinary iron. For the ordinary transformer consisting of a perfectly subdivided core of iron not infinitely soft and a primary and secondary coil, we would substitute an imaginary transformer consisting of a perfectly subdivided core of iron free from hysteresis, a primary coil, a secondary coil, and a third closed coil of suitable resistance. The current in this third coil would coincide with that in the secondary coil, and its exciting power would be added to that of the secondary coil. For example, let the volume of iron affected by hysteresis in a particular transformer be 1,000 cubic centimetres, and let the energy of hysteresis be 5,000 ergs: the total energy dissipated would, with 80 cycles per second, amount to 40 watts. If the electromotive force produced in the secondary coil be 100 volts, then our imaginary third coil would have either the same number of turns as the secondary

coil and a resistance of 250 ohms, or it might have half the number of turns and a resistance of 62.5 ohms, or any other combination giving the same loss of energy. The mean value of the netitious exciting power would in all cases be the same, viz., the number of turns in the secondary coil multiplied by 4 ampere. Let, in Fig. 5, OH represent the maximum value of this exciting power due to hysteresis, then the total exciting power tending to demagnetise the core and which must in a certain measure be balanced by the exciting power of the primary coil, is represented by the length OI —being the sum of OH and HI , where HI equals OH of Fig. 4—and the point I will be pushed higher up as compared with Fig. 4. The net result of this alteration is an increase in the amount of energy which must be supplied to the primary coil. It is thus possible to include the effect of hysteresis in the geometrical methods of representing the working conditions of a transformer. I have dwelt at some length on this question, because, notwithstanding its apparently somewhat abstruse character, it is really of very great practical importance. In some transformers the heat generated in the iron core is in excess of that generated in the copper coils, even at full output. Now, where transformers are placed in parallel between high

potential mains, it is, for obvious reasons of safety, not advisable to allow customers to handle a switch on the primary circuit, and the current must therefore be on, whether lamps are being lighted from the secondary or not. When the supply is continuous, as it obviously must be in a general system, the cyclic changes of magnetism in the core of every transformer will be kept up day and night; and the question of heating becomes of far greater importance than is the case in dynamo machines, which, as a rule, are only worked for a certain number of hours per day.

On the basis of the foregoing we can now investigate the relative merits of the Gramme and Zepernowski rings, and the best proportion of copper to iron in each. I have selected the two original types and one modification of each as being fair representatives of the two large classes into which in the beginning of this paper I have divided all transformers. These "rings" are both equally difficult to manufacture, and contain serious practical defects; but from a purely electrical point of view they are regarded as good as the majority of transformers now in the market. Their practical defects constitute for my purpose a positive advantage, because nobody will care to claim either as his special type, and I shall thus escape the somewhat inveterate task of having to compare the actual transformers made by rival manufacturers. As it is obviously impossible to conduct an investigation of this kind on absolutely general lines, it was necessary to assume rings of definite dimensions. I have selected rings of circular section having an internal diameter of 20cm. and an external diameter of 42cm., shown in full size in the wall diagrams (Figs. 2 and 3). The mean primary potential is assumed to be 2,000 volts, and the secondary 100 volts. The copper coils in Fig. 2 and the coils forming the iron shell in Fig. 3 are supposed to touch each other on the inside, and, being of equal depth all round, to separate on the outside, exposing part of the inner ring. In the Zepernowski transformer as actually made the inner diameter of the ring is rather smaller than shown in Fig. 3, and the shell winding covers the whole surface of the conductor, being of less depth on the outside than on the inside; but the magnetic resistance is in either case so low that the difference between the assumed and actual arrangement does not materially affect the result, whilst the calculations for the former are somewhat less complicated. The total space occupied by insulation I have assumed to be 1cm., or 2.5mm., between the core of the Gramme ring and the primary coil, and 2.5mm. between that and the secondary coil. The same space has been allowed for the Zepernowski ring. We can now assume different sectional diameters for the inner ring (core or coils), and depth of winding for the covering (coils or shell), so as to make up the 11cm. sectional diameter of the whole ring; and determine the output for each combination so that for continuous work the apparatus should keep moderately cool. From analogy with dynamos I estimate the total energy which may be wasted without producing overheating at 260 watts, and the output has in all cases been calculated on this basis for an induction of 8,500, a periodic time of 1.80sec., and hysteresis at 5,000 ergs. As it would serve no useful purpose to burden this paper with a reproduction of the somewhat lengthy calculations, I have plotted the results in the curves II. (Figs. 6 and 7). The curves I show the output which might be obtained if hysteresis did not exist, in which case the whole of the 260 watts would be transformed into heat within the coils. The thickness of copper winding (Fig. 6), and that of the iron shell (Fig. 7), is plotted on the horizontal, the output on the vertical. From Fig. 6 it will be seen that the maximum output with the Gramme ring is 6,400 watts with a thickness of copper winding of about 1.7cm., leaving 6.6cm. for the sectional diameter of the core. The cross-sectional area of the magnetic circuit is in this case about 80 per cent. of the cross-sectional area of the electric circuit, and the gross volume occupied by iron is about equal to the gross volume occupied by copper. The maximum output for the Zepernowski ring (Fig. 7) is 6,100 watts for an iron shell 2cm. thick, leaving the sectional diameter of the coils 6cm. The cross-sectional area of the magnetic circuit is in this case nearly eight times that of the electric circuit, and the gross volume occupied by iron is 14 times that occupied by copper. Thus, with the same external dimensions, the Zepernowski ring gives a slightly lower output than the Gramme ring; but it must be remembered that the weight of copper is also slightly smaller. I have made the same calculations for oblong rings, as shown in Fig. 8. Imagine the Gramme ring cut in halves, these straightened and laid side by side, and the two cores joined by semicircular pieces at the ends. The copper coils will in this process not be altered, but the length of the magnetic circuit and the volume of iron in the core will be increased, hence more energy will be absorbed in hysteresis, and the output will be reduced. In Fig. 6 the curve 2 represents the output for the oblong Gramme ring. By adopting the oblong shape for the Zepernowski ring we do not alter the mass of iron in the shell, but we lengthen the electric circuit, and increase the waste of energy in the coils. In this case also the curve of output 2 (Fig. 7) must be below that of the circular type. Curve 1 (Fig. 7) shows the output of the oblong type if there were no hysteresis. In Fig. 6 this must obviously coincide with curve 1. The maximum output of the

oblong type is for the Gramme ring, a little over 6,000 watts; and for the Zepernowski ring, 5,800 watts.

Up to the present we have only considered the output as limited by the amount of energy which may be wasted without overheating. But there is another and equally important consideration which affects the output, namely, the question of self-regulation. It is evident that in a transformer fed at a constant potential the induction is a maximum when the secondary circuit is open, for in this case the counter electromotive force of the primary is very nearly equal to the electromotive force at the terminals. At full work the two differ by the amount lost in resistance, and the induction is reduced in the same proportion. The electromotive force generated in the secondary coil is proportional to the induction, and we must deduct from it the loss in resistance in order to obtain the external electromotive force. Thus, if 1 per cent. be lost by resistance in the secondary, and 1 per cent. by resistance in the primary, the difference of available electromotive force between open circuit and full output will be 2 per cent. For good lighting this may be considered the permissible limit of variation, and on this basis I have calculated the output of the four transformers above described. Curve III. in Fig. 6 gives the result for the circular and oblong Gramme ring. It will be seen that with a stout core the limit of output due to heating is reached sooner than that imposed by the condition of self-regulation, whilst for thin cores the reverse is the case. The best proportion of iron to copper is indicated by the intersection of curves III. and II. for the circular, and III. and 2 for the oblong transformer. In the latter case the core would have to be 7.2cm. in diameter, and the winding would have to be 1.4cm. deep. The output is 5,900 watts. For the Zepernowski ring curve III. gives the output as limited by self-regulation in the circular, and curve 3 in the oblong type. The diagram shows that the limit of output imposed by the condition of self-regulation is in all cases reached sooner than that due to heating. For the oblong transformer the maximum output is slightly below 5,000 watts, and the best proportion of iron to copper is given by the abscissa of the highest point of curve 3. The external shell would have to be 2.4cm. thick, and the sectional diameter of the coils 5.2cm. From the above figures it appears that in the circular and in the oblong type the Gramme ring, dimensioned as shown in Figs. 2 and 3, gives more output than a Zepernowski ring of the same over all dimensions, the latter is therefore not superior to the Gramme ring, as commonly supposed, but somewhat inferior.

It might be, perhaps, objected that I have selected proportions different from those found in actual circular shell transformers, which have a much stouter ring of smaller mean diameter. More of the internal space is filled by the shell, and the central hole left is much smaller than shown in Fig. 3. The iron wire forming the shell is not put on in regular layers, but the turns cross each other in a more or less confused manner. There is no objection to such winding from an electrical point of view, as perfect insulation between the wires is of small importance. For the Gramme ring such winding would, on the other hand, be quite inadmissible; and it is on this account that I have selected a somewhat larger internal diameter of the rings, which gives room for regularly wound coils. But even if the rings are much stouter their proportion of output is not materially altered. If we imagine the ring of Fig. 3 contracted so as to reduce the central opening to 10cm. and the extreme diameter to 32cm., we obtain about the proportion of a Zepernowski transformer.

For convenience of calculation I have assumed a ring of these proportions to be changed into the oblong type, as shown in Fig. 8, but with this difference—that the external winding (coils or shell) on each side is only 15.7cm. long instead of 31.4cm., the diameter being 11cm., as before. Calculating the output in the same manner as before, I find that for the core transformer the maximum output as limited by heating is 3,230 watts, and is reached when the copper winding is 2cm. deep; whilst the maximum output as limited by the condition of self-regulation (within 2 per cent.) is 3,020 watts, and corresponds to coils wound 1cm. deep. The two curves cross each other, as in Fig. 6, and the ordinate of the crossing point corresponds to a maximum possible output, as determined by the joint limit of heating and self-regulation, of 2,950 watts with coils wound 1.3cm. deep. In the shell transformer the limit of output due to heating is 3,030 watts when the shell is 2cm. thick, and the limit of output due to self-regulation is 1,650 watts when the shell is 2.2cm. thick. These figures show that even in stout rings, having proportions more nearly comparable with those of the Zepernowski transformer, a actually constructed, the core type is better than the shell type.

This result refers, however, only to transformers having a core or a shell of circular section; and the question is whether by an alteration in the form of the shell the shell transformer could be improved. Any departure from the circular form of the shell must increase the length of the magnetic circuit, and must so far be detrimental; but if we can at the same time reduce the length of the copper coils, this disadvantage may be more than balanced by the reduction in the resistance of the circuits. As

a matter of fact, the magnetic resistance of the shell is so low that even a considerable increase in the length of the magnetic circuit does not materially affect the difference of phase between the primary and secondary current. The two are almost diametrically opposed whatever may be the magnetic resistance. We can, therefore, adopt any shape of shell which will allow the length of the copper coils to be reduced. This is actually done in most modern transformers. The shell is rectangular, with the short side of the rectangle parallel to the plane of the coils, and thus the mean diameter of the coils is reduced. In addition to this, the circular form of coils has been abandoned in several of the more modern transformers, so that the shell may fill more or less completely the interior of the coils.

In core transformers as now generally made the coils are not arranged all over the core, but are disposed in two sets, one on each limb of a single core. Each set of coils contains a primary and secondary circuit wound upon each other, or one between the other, so as to obtain perfect symmetry. Were this not so, and were one limb wound with the primary and the other with the secondary, external poles would be formed at opposite points of the core, and the output would be reduced. In a similar manner the coils in shell transformers are wound upon or in between each other, but there is generally only one set of coils and a double core. The distinctive characteristics of the two types are therefore as follows.

Core transformers—One core and two sets of coils.

Shell transformers—Two cores and one set of coils.

The following are some of the principal modifications of each type:

Core transformers—Gaulard and Gibbs, Lowrie-Hall.

Shell transformers—Zipernowski, Ferranti, Morley, Wright, Kennedy, Statter, Westinghouse, Snell and Kapp, Gaulard and Gibbs.

As most of these transformers are on the table, I need not describe them at length. The original Gaulard and Gibbs transformers had an open magnetic circuit, and cores which could be more or less inserted into the coils so as to regulate the E.M.F. of the secondary—a provision obviously necessary where the transformers are coupled in series. In the apparatus shown in 1883 at the exhibition in the Aquarium, there were four distinct induction coils, and in that employed for lighting on the Metropolitan Railway in 1884 there were 16 distinct induction coils, the circuits being formed by a compound cable consisting of a central primary wire and six secondary wires grouped round it. In 1885 was introduced a type of transformers with closed magnetic circuit, in principle identical with that shown in Fig. 8, but the two limbs further apart. In the same year Messrs. Gaulard and Gibbs introduced small shell transformers in their Tivoli installation, each transformer feeding one 50 candle power lamp. The two circuits are formed by a compound cable coiled into a solenoid, through which is passed a bundle of iron wires, the projecting ends are then bent over to close the magnetic circuit on the outside of the solenoid, and the whole is enclosed in a perforated metal cylinder with wooden ends. In their latest design of transformer the coils are circular in plan and rectangular in section, and are surrounded by groups of U-shaped soft iron stampings slipped over from both sides and held together by two circular cast-iron plates with a central bolt. The primary circuit is split up into two coils, with the secondary between them.

In the Lowrie-Hall transformer there are two sets of primary and secondary coils, laid horizontally one above the other. The core is formed by thin, broad sheets of soft iron insulated from each other by varnished calico, and the projecting ends of these plates are alternately bent up and down respectively so as to complete the magnetic circuit, the whole being clamped together in a horizontal cast-iron frame. The Ferranti transformer is similar in the mechanical arrangement, but, belonging to the shell type, has only one set of coils of rectangular section. The core is formed of thin iron strips of moderate width insulated from each other, doubled over at the ends, and clamped in a cast-iron frame. Mr. Rankin Kennedy has devised various transformers of the shell type. For the general supply of alternating currents he proposes to use a main current transformer at the generating station, in which currents from low-tension dynamos are to be converted into high-tension currents to be sent into the mains. The shell of this transformer is built up of moderately wide but very thin strips, to form a rectangular frame of considerable depth, the strips being fastened by bolts at the corners. The core is composed of a series of strips of double width passing like a web through the middle of the opening of the rectangle, and thus subdividing it into two openings through which the winding passes. In another type, which Mr. Kennedy calls the "piled form of subdivided transformer," the iron portion consists of H stampings, in which the central web forms the core and the two down strokes of the H the shell, the coils being wound over the web. A number of these wound frames are piled upon each other, and side by side, the whole being clamped between cast-iron covers. Diagrammatically, this construction can be represented by Fig. 1 if, instead of employing only two links, we use a number of them formed into a chain consisting alternately of copper and iron circuits. In another form of apparatus

Mr. Kennedy uses a Siemens shuttle armature overwound with a shell of iron wire. Mr. Wright's transformer may be described as a Zipernowski ring with coils of rectangular section and a shell of rectangular iron frames instead of the original iron winding. Each frame is cut across a corner, so that it may be placed over the core; and as the edges are packed close on the inside, but radiate on the outside of the ring, the frames form gills for the dissipation of heat. In Mr. Morley's transformer the shell consists of thin rectangular iron plates with a rectangular opening, the strip cut out being laid across the frame to form the core of the coils. The ratio in the length of the sides of the rectangle must evidently be as 4:6, and that of the strip cut as 2:4, in order to obtain a uniform section throughout the magnetic circuit. The apparatus is built up by alternately slipping a frame over and a strip through the coil. The core of the Westinghouse transformer consists of rectangular frames, each with a central web connected to the frame on one side only, so that it can be bent back to slip over the coils. The whole is mounted in a cast-iron weather proof box for outdoor use. The shell in Mr. Statter's transformer consists of E shaped stampings slipped over the coils alternately from either side. To obtain the same area of iron throughout, the width at the bottom of the stamping is twice that of the limbs. In the transformer designed by Mr. Snell and myself the shell consists of U stampings forming a double trough into which the coils are laid. The covers of these troughs are formed from the metal removed from the interior of the stampings. The whole is held together in a cast iron frame so arranged as to allow air to circulate through the core and round the coils.

To render transformers perfectly safe it is necessary to avoid leakage between the two coils. For this purpose Mr. Kent has devised a very simple apparatus, consisting of an insulated sheet of metal wrapped round the inner of the two coils, but not forming a closed circuit in itself. This sheet of metal, which thus separates the two coils completely, is connected to earth. Now, if the insulation of the primary coil should fail, the leak, before reaching the secondary coil, must pass through the sheet of metal, and is thus conducted to earth, causing the primary cut-out to melt, and thus cutting the faulty transformer out of circuit. Another safety appliance has been devised by Captain Cardew. Its object is to disconnect the primary circuit from the mains if any part of the secondary circuit acquires a certain potential above that of the earth, which will take place if a leak occurs between the two circuits. The apparatus consists of a cast iron box on the bottom of which is laid, into a shallow recess, a strip of platinum foil terminating at both ends in circular discs. About one eighth of an inch clear above one of these discs is set a metal disc with screwed stem at the back passing through the glass cover of the box, and connected by a fine fuse wire with any point of the secondary circuit. The box itself is connected to earth. The fuse wire holds back a contact spring so arranged that on breaking of the wire it will fly down to its contact and short circuit the primary terminals of the transformer, after which its own primary fuse will melt and cut off the supply of current. If the potential between earth and the insulated disc in the box should rise above a certain limit (which can be regulated by screwing the disc up or down) the static attraction between the disc and aluminium foil lifts the latter into contact, allowing a leakage current to pass through the fuse wire of the contact spring, and thus releasing the latter. I am told by Captain Cardew that this apparatus has been tried at the Grosvenor Gallery installation, and been found to act in a perfectly reliable manner.

In the present paper I have only dealt with what may be called elementary principles in the construction of transformers. As, however, the application of transformers is a matter of far greater importance to our profession at large, I trust you will allow me to say a few words on this subject, not with the object of imparting information, but in the hope that a discussion of real practical value may be the result. Up to the present, distribution by transformers has been made either on the single-series or the single-parallel system; compound parallel, the three wire system, or any other refinement of direct-supply methods, have, to my knowledge, never been attempted with transformers. The series system must fail for want of self-regulation where the lamps are to be connected in parallel and controlled independently of each other, but for very extensive and sparsely-lighted districts, with the lamps supplied by each transformer in series on the Bernstein system, a series arrangement of transformers will admit of perfect self-regulation, provided the primary current be kept constant, and will, moreover, be cheaper than the parallel system. For general purposes, and especially for the dense lighting required in towns, the only practical method at present in use is to connect the primary terminals of the transformers all in parallel, and the lamps also in parallel, across the secondary circuit of each transformer. In principle this arrangement is adopted in England, America, and on the Continent, but the methods differ in these countries. Here the distribution is made by a high-tension network of mains, and the transformer of each subscriber is directly connected with the mains. In America a double network of overhead mains is employed, one for the high-tension and the other

for the low tension currents. These mains are supported generally on the same poles, to which are also fixed the transformers, and the subscriber's connection is made with the low-tension mains wherever convenient. On the Continent a network of low-tension underground mains is used for distribution in the same way as if the supply were on the direct system, and this network is fed by alternating currents at certain points where fairly large transformers are installed. The primaries are connected with the station either by overhead wires or by a special kind of cable containing two circuits insulated from each other and arranged concentrically. The cable is protected by a double lead covering and by an iron sheath formed of spirally wound tape. Of the three methods here described our own appears to be the worst, the American slightly better, and the Continental the best. To string high-tension wires over and across our streets, allow high-tension branch leads to pass into our houses, and give every subscriber a little transformer to himself, more or less within the reach of the inmates, seems to me to be positively counting disaster. Such rough and ready methods may do as long as the light is not generally installed throughout a district; but once assume that every householder is using it (and it is that we are hoping for), the thousands of branch wires and transformers in the houses must constitute a very serious element of danger. In the American plan the high-tension wires are not brought into the houses, and in so far there is little danger to the inmates, but, of course, in the streets there is the same danger as here from the overhead wires.

Now the Continental plan may almost be called absolutely safe. With an arrangement like Mr. Kent's dividing sheet to prevent leakage, or Captain Cardew's ingenious apparatus for detecting it and cutting off the supply, the secondary circuit can never acquire a potential sufficiently high to endanger life or property. This network can be composed of comparatively light cables, because we can feed it at frequent intervals and thus insure constancy of pressure at all places and at all hours. The transformers would be fairly large, say from 500 to 1,000 lights each, and could be installed in rooms to which no person but the authorized attendant has access, and by placing the primary feeding mains also underground accidents would be rendered almost impossible. The method of using an underground secondary distributing network has also the advantage that, should at any future time storage batteries become sufficiently improved to render distribution by continuous currents possible, the whole of the cables would be available for this purpose without any change.

ELECTRICAL MEASUREMENTS, ESPECIALLY AS APPLIED TO COMMERCIAL WORK.

BY PROF. WM. A. ANTHONY.

(Continued from page 116.)

A form of instrument known as the Wirt voltmeter, as furnished by the Electrical Supply Company, of Chicago, uses the Daniell cell, of special construction, as a standard. The cell consists of three square bottles cemented together side by side. In one of the outside bottles is the zinc in zinc sulphate, communicating with the middle bottle by a small hole near the top. The other outside bottle contains the copper in copper sulphate and communicates with the intermediate bottle by a hole near the bottom. In the middle bottle is a valve which when closed prevents communication between its upper and lower parts, and prevents the mixing of the two liquids. This valve is to be opened only at the time of making an observation. No doubt such a cell made up from pure materials would give the same potential for a considerable time.

I have so far avoided the use of the term electromotive force for I find there is a good deal of confusion as to the exact use of it among physicists. I find it stated in some works of high authority that electromotive force and difference of potential are synonymous terms, and again that difference of potential produces electromotive force. I have seen it stated in a very excellent text-book on electricity by one of our foremost electricians, that the electromotive force of a voltaic cell is the result of the difference of potential between the poles.

I can best illustrate what I conceive to be the difference between the two terms by referring again to the analogy between the electric flow and the flow of fluids. Gas is flowing through the pipe. Take two points, A and B, and suppose the flow to be from A towards B. A pressure gauge would show a higher pressure at A than at B. Water flows in your water mains. A pressure gauge will show a higher pressure at any point than at any other point further on in the direction of the flow (it is supposed that the points considered are at the same level). The difference of pressure is the cause of the fluid flow. It is the force that moves the fluids, the fluid-motive force. Electricity is flowing along this wire.

I have shown that there is a difference of potential between the different points along the wire, and we accept that difference

of potential as the cause of the electric flow between the two points. If we know nothing of the pipe except between the two points considered, we cannot assign any other cause for the flow of the fluid through it except the difference of pressure, but we know the difference of pressure must have a cause, and if we are at all inquisitive we shall not be satisfied with saying the difference of pressure is the fluid motive force, but we shall trace the pipe back and try to discover the cause of the difference of pressure. Tracing the pipe back we find, by-and-by, a stand-pipe in which the water level is far above any of the outlets from which water is drawn. This accounts for the pressure of the water in the pipes, but still we are not satisfied. There must be a cause for the high level in the stand-pipe. Investigating further, we find a system of pumps which forces the water into the stand-pipe, taking the water, perhaps, from the same level to which our pipes discharge it. Here we find a water-moving force that is not water pressure, without which the pressure that moves the water in our pipes would soon cease, and the flow stop.

Suppose now that all our outlets are stopped, and that no water flows from the stand-pipe. What results? The pumps go on working, the water in the stand-pipe rises higher and higher, and if the pipe is high enough and strong enough the water will rise till the force of the pumps is balanced, and they will stop. The pressure now exerted by the water column measures the water-moving force of the pumps. We can tell by it just what is the force we have at command for moving water. This force is the water-motive force of our system. It must be sufficient to overcome the resistance of our pipes, and carry the water to the highest levels we wish to reach when the flow is most rapid. Open a cock, the water flows and lowers the level in the stand-pipe, the back pressure upon the pumps is diminished, they begin to work, and maintain the water at nearly its former level. Open another cock, the levels falls a little more, and the pumps work faster. Make more and more openings and the water in the stand-pipe falls more and more till, by-and-by, the level in the pipe is but little above that of the supply from which you pump. Water is being used at such a rate that the force of the pumps is little more than sufficient to drive the water through their own passages. It is not the water-motive force that has failed, but the carrying capacity of the pumps.

Now note the analogy in the case of the voltaic cell. We have found on this wire a difference of potential from point to point. Trace the wire back and we find an apparatus whose office it is to maintain the potential difference. What is its action? By some means, which we do not understand as well as we understand the action of a water pump, this apparatus takes electricity from one of the plates, N, in the liquid and forces into the other, P. In the second plate, P, the electricity is at a higher level, and so flows through the wire to the plate N to be forced back to P through the liquid. Cut the wire and almost at once the electricity in P reaches the highest pressure, level, or potential, that the cell can produce. All action in the cell ceases, and the difference of potential between it and P now measures the force the cell can exert to move electricity, the electromotive force of the cell. The electromotive force is something that depends upon the materials of which the cell is made and is absolutely independent of its size. The smallest cell, one made of a copper metal cup holding a drop of water, and a bit of zinc of the size of the point of a pin, as I have often shown experimentally, has the same electromotive force as a cell of the same materials of the largest size; just as the water-motive force of a small pump, its power to produce pressure may be just as great as that of a larger one. Let us follow the analogy. I connect P with N by a small wire. This is like opening a single stopcock on our water service. The electric level is lowered, but the cell begins to work and maintains the potential at very near its highest value, another wire allows more electricity to flow, still more lowering the potential, and it is possible to open so free a path for the passage of the current that the cell can no longer maintain a considerable potential difference, and the limit of the capacity of the cell to supply electricity is reached.

Note that the limit here is not due to any falling off of electromotive force, but to the fact that nearly the whole electromotive force is required to carry so much electricity across the liquid from plate to plate. Here exactly is the advantage of a large cell over a small one—a large cell, like a large pump, can maintain a high pressure, even when there is a large draft upon it. I think you will now see the distinction between the terms difference of potential and electromotive force. Difference of potential is one electromotive force. But the general term, electromotive force, includes all causes of the movement of electricity. There may be a flow of electricity without a difference of potential, but there can never be a flow without an electromotive force.

I could give you examples of a great variety of electromotive forces, but one more will suffice.

I move this rod across the earth's magnetic field. I know that an electromotive force is developed, causing a flow towards the end at my left hand. That end, I am sure, is for the moment at a higher potential. When I stop, the electricity flows back and equalises the potential. Connect the two ends by a wire leading to a sensitive galvanometer, and the flow of current is demon-

strated. This movement of a wire across any magnetic field develops a difference of potential between the two ends, and if the wire form a closed circuit, a current will flow. I said just now that we could have a flow without difference of potential. Here is a case. A magnet thrust end-on into the centre of a wire hoop produces an electromotive force, which acts equally all round the hoop, causing a flow, but without difference of potential. Here, too, we may find an analogy in the flow of liquids. Suppose a trough in the form of a ring to contain fluid, and let an endless rope be laid in it, and made to move around the trough (Illustrated on black board.) The liquid will be dragged along by the rope, but there is no difference of pressure or level anywhere.*

Following out this analogy to fluid motions is very useful in leading to clear views of very many other electrical phenomena, for, although nothing is really explained, an unfamiliar fact seems to us more plausible when we find in it a close analogy to a fact with which we have been long familiar, and about which we have no question. Take the case of the operation of electric motors. We know that an electric motor develops an opposing electromotive force, and every electrician knows that this opposing electromotive force is the secret of the operation of the motor, that mechanical power cannot be developed without it, but I find that few people except those familiar with the theory are willing to believe that this counter electromotive force is of any use. I have known of some motors being constructed with the avowed object of reducing the counter electromotive force as much as possible, with the idea that it was a hurtful resistance, preventing the motor from developing its full power. But how is it with a fluid flowing through a pipe? In order to make it do work we must construct a machine to produce a counter pressure. A water motor always checks the flow of water.

Take the simple case of a rotary motor. (Rotary motor on blackboard.) Let it run at full speed, and suppose there is no friction. It offers no resistance to the flow of the water. The water flows with the same velocity as though the motor were not there and it does no useful work. Begin now to load the motor, you check its speed and at the same time check the flow of water. As you increase the load you check the flow more and more. The force exerted upon the motor will be greatest when it is brought to rest, and the flow in the pipe stopped; then the water will exert its greatest pressure, but since the motor does not move, it can do no work. Between these two conditions of no power to do work, when moving with the full velocity of the water but without force, and when receiving the full pressure of the water without moving, there must be a condition of maximum power, or maximum rate of working, and we can readily admit that this occurs when the back pressure of the motor is half the water-moving force. At this speed half the water-moving force is effective in running the motor and half goes to waste in the velocity with which the water leaves the motor. The efficiency of the motor is, therefore, only fifty per cent. It would be far better, if so much power is needed, to use a larger motor and run it at slower speed and at less than its maximum power, and let less of the energy of the water to go to waste.

Now, note the analogy between this and the electric motor. When the electric motor is running it develops a counter electromotive force which corresponds to the back pressure of the water motor. When this counter electromotive force equals half the electromotive force of the generator, the electric motor is giving its maximum power, but it is using only half the energy of the electric current, the other half going to waste in developing heat in the conducting wires leading to the motor, and in the motor itself. Just as with the water motor, it is better to use a larger size electric motor and let it run at such a rate that it will develop a counter electromotive force equal to more than half the electromotive force of the generator, and while developing less than its maximum power perform a work equal to a larger percentage of the energy given to it. The difference between the water motor, which I have taken for an example, and the electric motor, is this, that while the water motor exerts the greatest back pressure when it is stopped, the electric motor exerts the greatest counter electromotive force when it is running at the highest speed. Otherwise, the analogy between the working of the two is very close, and the efficiency of either one of them is exactly the ratio of the back pressure which it exerts to the possible pressure which can be brought to bear upon it.

In bringing this lecture to a close I wish to acknowledge my own obligation to Mr. Ives, who has kindly loaned and operated his lantern for projecting the views on the screen; to J. W. Queen and Co., for the loan of nearly all the apparatus used and exhibited here this evening, and to Mr. C. H. Richardson and Mr. Metzgar, of the firm of Richardson and Metzgar, who have given their services for the whole day, with the resources of their workshop, for the preparation of the apparatus for the experiments. Without their assistance the preparation of the experimental illustrations would have been impossible.

* (This statement, as well as that which it is intended to elucidate, is, we think, open to question.—Ed. E. E.)

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

STUDENTS' MEETINGS.

At a meeting of students on January 19, F. H. Webb, Esq., presiding, a report of the committee was read and adopted. The following gentlemen were elected to form a students' committee for 1888:

Messrs. C. G. Lamb, B.Sc., Chas. Priest, J. N. Cooper, R. W. Paul, E. G. Fidd, A. G. Samuels, and John Rance, jun. (hon. sec.). Mr. J. N. Cooper then read a short note upon "An Error due to Refraction in Mirror Galvanometers." A discussion followed, in which Messrs. Paul, Smith, and Lamb took part.

At a students' meeting on the 2nd inst., Prof. J. A. Fleming, D.Sc., in the chair, Mr. C. G. Lamb, B.Sc., opened a discussion upon the recent papers upon Voltmeters. Messrs. Cunningham, Smith, Paul, Date, Dykes, Cooper, and Dr. Fleming discussed the subject, and after Mr. Lamb's reply the meeting was terminated by thanking Dr. Fleming for presiding.

COMPANIES' MEETINGS.

ANGLO-AMERICAN TELEGRAPH COMPANY.

The half-yearly general meeting of the Anglo-American Telegraph Company (Limited) was held on February 3rd, at Wimpster House, 111 B. and St. street.

The Right Hon. Viscount Monck presided, and in moving the adoption of the report observed that there had been a large increase in their traffic, which, however, had not yet become remunerative. The working expenses had been very much the same as they were in the corresponding period of the previous year, but in the general expenses there had been a considerable increase, owing to the repair of the 1869 cable—an event which appeared to him to be so important as almost to mark an epoch in the history of telegraph construction and repairs. It was to be borne in mind that the cable had been 18 years under water. It broke at a depth of 2,750 fathoms, and to be repaired it had had to be lifted from a depth of 2,300 fathoms. That work had been done by their own ships—the "Mina," and great credit was due to Captain Trott and the officers and crew for the ability, energy, and skill which had been displayed by them. They had also had to transfer the shore ends of the cables at Valencia from their original position, where they were subject to abrasion from the roughness of the bottom on which they were laid, to another spot, where they rested more easily, and with less risk of injury. The 1869 cable had been several times in repair, but there were extensive lengths of the cable which had never been stressed or sustained any injury. The faults in the cable mentioned had been effectually removed by Captain Trott, but he regretted to say that since that the cable had again given out in a depth of 1,500 fathoms, and at a distance of 1,000 miles east of the previous break. Their contest in the law courts in Paris with the French Company for leaving the "pool" had been so far settled entirely in the Company's favour, but until the appeal of the French Company had been settled, they could not consider themselves out of the difficulty. A matter of much more importance was the contest which the Company and the associated companies were engaged in with the Commercial Cable Company of America. If, however, there was any moral turpitude in instituting a fighting tariff, they were not the offenders, for the rate was 2s. a word per to the working of the Commercial Company, who reduced the charge to 1s. 6d., they themselves being, of course, then obliged to adopt that tariff. That was the state of matters 18 months ago, when the Board, after a careful consideration of the case, came to the conclusion that the only policy they could adopt was to reduce the tariff, not for the purpose of fighting, but for the purpose of stimulating traffic, with the object of gaining a large revenue from a low tariff. That object was fully stated by him at the time, and it was accepted by the great body of the shareholders as a wise and proper policy to adopt. He was still of that opinion. He at the same time carefully guarded himself against naming 6d. or any sum as the ultimate point at which the tariff should be fixed. As he had predicted, the adoption of such a policy had made a considerable demand on their patience and forbearance, and he was sure that no one regretted the fact more than his colleagues and himself. Their traffic was now 162 per cent. larger than it was before the 6d. rate was adopted, but, unfortunately, that was not enough to give them a remunerative revenue. For the first year of the 6d. rate the increase in their traffic was very great, but last year the increase was only 12 per cent. Although that ought in time to grow to a very much larger extent, he was afraid that the trial of their patience meanwhile would be so great that it would reach what was called the straining point. He thought they had tried the 6d. rate to its full extent, and he did not think there was that element of increase in the traffic which promised to render it remunerative to the shareholders. The question was, what were they to do? They had had meetings with representatives of the Commercial Company, but they had got to nothing, it being impossible for them to subscribe to the demands of that company. At the meeting recently of the Direct United States Company, Sir John Pender threw out a hint that there ought to be another conference. He (the speaker) confessed that his experience of the past did not render him very sanguine as to the result which such a conference might bring forth, but if Sir John Pender could induce the other parties who were interested to go into a conference they themselves would not hold back.

The Marquis of Tweeddale seconded the resolution.

Mr. Thomas Smith of York supported the motion, observing that he regarded the report as a moderately satisfactory one. He considered that the 6d. rate had now had a fair trial, and if the shareholders were satisfied with the present dividend that rate might be continued. Mr.

however, suggested that it should be reduced to 3d. "No no", believing that that would terminate the war which, in his opinion, had now arrived at a point when one side must give way. The market value of the investments bearing their proposed bond was only £5,000 short of £11,000,000, and their financial position was therefore a very strong one.

Mr. Chester regretted to hear such a proposal as a reduction of the tariff to 3d. a word. In acting as they were now doing they were simply carrying out the policy which they had pursued for the last 15 years. The policy of carrying out opposition had, however, brought no benefit to the shareholders, and had he maintained, simply led to other cables being laid. It was impossible for them to succeed in their claim to have the whole of the cable traffic across the Atlantic. He believed that if the rate were raised to 9d. a word it would pay the company and meet the wants, the growing wants, of the commercial community.

Mr. Wood suggested that 9d. a word might be charged for express messages, and 6d. a word for ordinary messages.

Mr. John Newton said it seemed to him that in the past there had been nothing but a "squaring" of the accounts of the Company, and that as soon as a compromise was made another competing cable was laid. They must adopt a policy of downright fighting rates, and a policy of laying new cables at less than their cost price.

Mr. Jackson complained of the management, and said that the result of what had been done in the past two years had been to give the proprietors a return on their capital of £1 6s. 3d. per cent. per annum. He was glad to hear what had been said in regard to another cable.

Other gentlemen having addressed the meeting, the Chairman, in reply, at the close of the discussion, stated that by the decision with respect to the French Company, the Company had been awarded a premium of about £30,000 and 2,000 miles for every day that the French Company adhered to their resolution to abandon the "pool." As, however, he had already said, that decision had been appealed against. The law would not allow them to charge a rate for express messages. He could understand Mr. Jackson's impatience at the result which had been obtained, but not with the management of the Company. The directors had done the best they could, fighting against facts which could not be changed. Mr. Humphreys had said that the repairs had been paid for out of revenue they could have obtained elsewhere. That was so, but then the revenue fund had been expended for the very purpose for which it had been used during the war. In regard to Mr. Dealy's remarks, the cost of the cable was about £200,000, which was a very small sum for the cost of a new cable. If for no other reason, and just it would be worth their while to repair the cable and keep it in a state of law, a cable would remain effective in the Atlantic. That was the oldest cable working in the Atlantic. The Atlantic was of much better construction.

The report was adopted, and the retiring directors and auditors were re-elected.

At the motion of Mr. Jackson, seconded by Mr. Stockdale, a resolution was adopted expressing the thanks of the meeting to the Captain, the officers and crew of the steamship "Mama" for the courage and ability displayed by them in connection with the repair of the 1869 cable.

CUBA SUBMARINE TELEGRAPH COMPANY.

The ordinary general meeting of the Cuba Submarine Telegraph Company, Limited, was held on Wednesday at the offices, Old Broad-street. Mr. Jaquin de Mancha, who presided, stated that the number of messages transmitted had increased in the past half year, and, compared with the same period of 1886, they had received £1,528 more. The company had been asked about the same, but the repairs had been £30 more. They were enabled to make the half yearly payment to the cable which they contracted for some years ago. That amounted to £1,875 and they had in hand sufficient to pay the premium, valued at the rate of 10 per cent. They also proposed a dividend on the ordinary shares at the rate of 8 per cent. He concluded by moving the adoption of the report.

Mr. Alexander F. Low seconded the motion. In answer to questions, the Chairman stated that the cost of the cable which they were paying for every half year was £48,000, of which they had paid £28,000. When the balance was paid the cable would belong to the Company. He thought that the way in which they had managed to pay for it was better than if they had bought it outright. The contractors agreed to keep a certain sum in the Company's possession to meet the cable required to be put in repair. Up to the present time, however, it had worked most creditably to the Messrs. Hooper. On Monday they received a telegram from Mr. Keith stating that the cable had not spoken. Mr. Keith, however, had found out where the fault was, and he believed its repair would not be very expensive. If the cable was to pay for the cable at once, the security they now had, in the event of its breaking, would disappear. The security in hand was £5,000. He thought it better to continue the existing arrangement.

The motion was adopted, and the dividends were afterwards approved.

PROVISIONAL PATENTS, 1888.

JANUARY 27.

1243. An improved portable electric lamp. Harry Lucas, Tom Bowling Lamp Works, Little King-street, and Ernest Edward Vaughan, 94, Trinity road, Birkbeck, both in Birmingham.

1250. An improved water wheel for driving electric generators, and its combination with, or application to such generators. Maria Immisch, 52, Chancery lane, London.

1254. Improvements in forming metallic connections with incandescent lamps and holders therefor. John Spink and Charles Gauzents, Sunbridge chambers, Bedford, Yorkshire.

JANUARY 30.

1364. Electric lighting for railway and other carriages. Frederick Johnson Martin, 101 & 102 Wood street, Chesham.

1383. Electric apparatus for use either as an electric motor or as an electric current meter. Francois Huel and Emile Picard, 68, Rue de la Loi, London, E.C.

1386. Improvements in telegraph insulators and appliances for suspending wires on aerial telegraphs. George Foster, 100, The Rye, Peckham, Surrey.

JANUARY 31.

1401. An improved pocket-compass. Albert Lloyd, 333, Lady-pool-road, Spalding, Rutland.

1406. Improvements to and in connection with electric time signals or alarms. Mary Tutton and Samuel Tutton, Du Dey-road, Tipton.

1461. Improvements in applying metals to metals by electric action or electric fusion, applicable more especially to obtaining a rough hard surface or a surface of a character other than that of the metal to which the said surface is applied, but applicable, in other cases where metals can be joined to metals by electric action or electric fusion. Robert Kirk Boyle, 47, Lincoln's Inn fields, London.

1479. Improvements in apparatus for indicating and registering payments, especially applicable for indicating and registering payments for the use of telephones. Alexander MacGregor, 47, Lincoln's Inn fields, London.

FEBRUARY 1.

1505. Improvements in the construction of electric brushes for curative purposes. Mary McMillin B. Quality court, W.C.

1525. Improvements relating to the distribution of electricity. Louis Edmond Schlegel, 45, Southampton buildings, London.

FEBRUARY 2.

1536. Magnetic and electric telephone and telegraph for transmitting and receiving musical vibrations or signals by means of electricity. James Battye, 15, Cross Park street, Batley, Yorkshire.

1557. Improvements in duplex telegraphy. Frank Jacob, 28, Southampton buildings, Chancery lane, London, W.C.

COMPLETE SPECIFICATIONS ACCEPTED.

MARCH 10, 1887.

3658. Improvements in alternating current transformers or induction coils. Robert Dick and Rankin Kennedy, 96, Buchanan street, Glasgow.

MARCH 17, 1887.

4070. Improvements in combined engines and dynamos. Matthew Henry Phineas Rait, Sarsley and Peter William Williams, 24, Southampton buildings, London, W.C.

MARCH 30, 1887.

4781. Improvements in electric batteries. The Electrical Power Storage Company, Limited, and Herbert William Butler, 47, Lincoln's Inn fields, London, W.C.

MARCH 31, 1887.

4809. Improvements in insulating electrical conductors. Eugenio Tortosa, 55 and 56, Chancery lane, London.

DECEMBER 28, 1887.

17,837. Improved means of generating electricity from heat. Philip M. Delaney, Junior, 55 and 56, Chancery lane, and Edward G. Ashton, (United States.)

DECEMBER 29, 1887.

17,886. Improvements in and relating to electro-magnetic marine governors. George Alexander Smith Gray's Inn chambers, 20, High Holborn, London, W.C.

DECEMBER 31, 1887.

17,965. Improved machines for cleaning windows, mirrors, and similar articles by either mechanical or electrical power. Francis Redmond, 120, San Hool road, Ranelagh, Dublin.

SPECIFICATIONS PUBLISHED.

1887.

1654. Closing secondary battery cells. W. Kingsland, 84.

2851. Automatic switch for electrical circuits. F. Parker, 84.

3197. Secondary batteries. Sir D. L. Salomons and others, 64.

4478. Supporting telegraph &c., wires. C. Maynard, 84.

11,448. Secondary batteries. J. S. Seiler, 84.

16,128. Mechanical telephones. W. H. Munro (Sunderland and Macclesfield), 84.

16,669. Combined secondary battery and miner's lamp. M. Roney and J. Warner, 64.

16,728. Incandescent electric lamps. A. Rowan, 64.

CITY NOTES.

West Coast of America Company. The traffic receipts of the West Coast of America Telegraph Company for January were £4,800.

Brazilian Submarine Company.—The traffic receipts of the Brazilian Submarine Telegraph Company for the past week amounted to £3,142.

Direct Spanish Company.—The traffic receipts of the Direct Spanish Company for January were £1,943, against £1,904 for the corresponding period of last year.

Great Northern Company.—The traffic receipts of the Great Northern Telegraph Company for January were £21,600, against £20,400 and £19,830 for the corresponding months of 1887 and 1886 respectively.

Western and Brazilian Company. The traffic receipts of the Western and Brazilian Telegraph Company for the week ending January 27, after deducting the fifth of the gross receipts payable to the London Platino Brazilian Company, were £1,764.

The Electrical Automatic Delivery Box Company.—This company is formed with a capital of £60,000 to acquire the patent and exclusive rights for the United Kingdom of Great Britain and Ireland of the Electrical Automatic Delivery Box, and the patent rights for India, New Zealand, Victoria, and Cape of Good Hope, invented by Messrs. Frank Villiers-Stead and Co. The cost, it is said, to erect a machine to deliver four articles will be about one-half the cost of machines now used. The possibility of the electrical automatic box being worked by false coin, wire, and shot is infinitesimal, whereas it is well known, in the other machines now before the public, frauds occur daily. It is stated that large orders have already been received to manufacture boxes for the Continent. The purchase price is £30,000, of which the vendor takes £20,000 in fully paid shares.

Submarine Telegraph Company. The report of the directors of the Submarine Telegraph Company for the six months ending December 31, 1887, shows a net result which enables the directors to add the usual proportion of the receipts to the reserve fund, to recommend a dividend at the rate of 15½ per cent. per annum, and to carry over a balance of £209 to the next account. The same dividend was paid in the corresponding period of 1886. The number of messages transmitted in the six months was 1,695,860, against 1,691,280 in 1886, but the length of the messages was only 11'03 words against 11'11 words. The Board has long been endeavoring to obtain a renewal of the French concession, and on three occasions within the last two years they have had strong grounds for believing that those efforts would be crowned with success. Unfortunately, the English Government have changed their policy, and propose to take into their own hands, at the expiration of the Company's French and Belgian concessions in January 1889, the working of telegraphic communication with Holland, Germany, Belgium, and France. This change of policy was communicated to the Board in a letter addressed to the chairman of the Company by the Chancellor of the Exchequer early in November, and the arrangements about to be concluded in Paris were thus frustrated. The Postmaster-General has since that time intimated the directors that Her Majesty's Government have decided not to grant any extension of the company's license for landing cables on the shores of this country, or to sanction a continuation of the working arrangement between the Company and the Post Office, as defined by the agreement of July 11, 1863, beyond the date fixed by that agreement. The Belgian Minister of Posts and Telegraphs has also informed the directors that it has been decided not to renew the concession granted to the company for landing cables on the Belgian shore. In these circumstances negotiations are being carried on between Her Majesty's Government and the Board, and when these negotiations are terminated the result will be made known to the shareholders without delay.

NOTES.

Halifax.—Attempts have been made to play a football match under the electric light, but the arrangements failed, and the match has been abandoned.

The Cruto Lamp.—According to *La Lumiere Electrique* the French patent for the Cruto incandescence lamp has been purchased by the firm of Rothschild.

Electric Lighting Act.—Lord Thurlow has re-introduced in the House of Peers his Bill of last session for amending the Electric Lighting Act, 1882.

Society of Telegraph Engineers.—The paper to be read on Thursday, Feb. 23, is "On the present state of telegraphy," by R. von Fischer-Treuenfeld.

Accumulators.—The Electrical Accumulator and Lighting Company, of Detroit, Michigan, have now nearly 1,000 lights in connection with their storage batteries.

Great Northern Railway.—At the half yearly general meeting of this Company, held at King's Cross Station on Wednesday, the proprietors were asked to sanction an expenditure of £520 for further electric lighting of the line.

Aluminium.—According to the *Western Electrician*, M. Charles Faure claims that the Cowles process for obtaining aluminium is his own invention, patented so far back as 1853. He has, it is said, taken steps to work the invention in question.

Preston.—In the notice of the proposed lease of tramways, the Corporation of the borough of Preston have inserted the following clause: "That the lessees are not to use any motive power other than animal power without the consent of the Corporation."

Windsor.—An electric light installation is being erected at Baron Schroder's country house by Messrs. Drake and Gorham. Two gas engines will be employed to drive the Edison Parker improved type dynamos suitably wound for charging 106 of Drake and Gorham's accumulators.

British Telegraph Wire.—The value of the telegraph wire exported from England during 1887 is estimated by *Electricity* at 20,427,425fr., as against 24,816,675fr. in 1886. A decree has been published by the *Mexican Commercial Journal* allowing telegraph and telephone wire to be imported free of duty.

Lighting in the Temple.—The electrical committee of the Inner Temple is canvassing the tenants of that Inn with the view of ascertaining how many of them wish to have their chambers supplied with the electric light. It is estimated by the committee that if the demand be sufficient the expense would not exceed that of gas.

New Cable.—According to the *Times* of yesterday, news has been received at Paris that the cable between Curacao and Venezuela has been laid. A vessel is laying the cable between Curacao and San Domingo, and will reach the latter country in two days, thus connecting San Domingo with Europe and with the United States.

Electricity and Gunnery.—An unexpected test of the 12 inch breech loading 45 ton gun on the sea face of the Haze Sand Fort at Spithead was made a few days ago. The gun was fired by electricity, the necessary arrangements for which were carried out by Master-Gunner Wilson. Three rounds were fired with perfectly satisfactory results.

The Brighton Railway.—From a report of the first annual meeting of the Ridsdale Lamp Company we gather that the Brighton Company is going to adopt their lamp, with the exception of those trains which are lighted by means of electricity. Of course, we should prefer to have seen the electric lighting extended. No doubt this will come in good time.

Buckingham.—The local authorities have given permission to Mr. A. C. Rogers to carry overhead wires across the highway for electric lighting purposes in the borough. Such permission has hitherto been refused because the applications were from companies outside the borough; but, as Councillor J. T. Harrison remarked, this differed in that it was from a townsman.

Maxim-Weston System.—It is understood that the Commissioners of Sewers have received an offer from this company for the lighting of the whole of the City by electricity. This information reached us too late to be dealt with in our leader, but we may take this opportunity of reiterating the moral of the leader that companies which interfere and do not initiate had better cease to exist.

Royal Institution.—Last Friday, at the Royal Institution, Mr. W. H. Preece, F.R.S., read a paper on "Safety Lamps in Collieries." The colliers of the future will have much to thank Mr. Preece for when the public mind has been fully aroused to the necessity of obtaining better and safer mining lamps. Mr. Preece has been indefatigable in testifying to the value of electricity as an agent for supplying a safe light in collieries.

A Long-Lived Lamp.—The ordinary guarantee of life for Edison's incandescent electric lamps is 600 hours, but one lamp in the *Globe* office has just gone out after a most extraordinary life. It was put in about the end of November, 1881, when the Edison system was installed in the office. It has continued burning ever since on the average 5½ hours every day, six days a week, making a total life of 5,292 hours. —*Toronto Globe*.

Glasgow Exhibition.—The united candle power nominal of the electric light to be used at this exhibition is equal to 1,090,000 candles, and the motor power will be produced by engines of 1,200 horse power. It is expected, as at Kensington, that the great attraction outside will be the Fairy Fountain, which, with its numerous jets, will be illuminated by electricity. The centre jet will throw water to a height of about 120 feet, and there will be about 100 jets altogether.

Draughts Playing by Telegraph.—A match is to be played by telegraph on the 2nd prox. between six of the members of the Melbourne Draughts Club and six representatives of South Australia. The similar fixture of a year ago fell through, owing to difficulties which need not be particularised; but it is confidently anticipated that the present match will be played. It is understood that owing to the pressure of business engagements, Mr. James Paterson will very probably be unable to play for Melbourne. —*Australasian*.

Earth Currents.—With a view to carry into effect the recommendation of the International Congress of Electricians at their Paris meeting in 1881, the Spanish Government is constructing two overhead lines entirely independent of the telegraph wires, and exclusively devoted to the investigation of the phenomena of earth currents. These lines will each be about five miles in length, one being parallel and the other at right angles to the magnetic meridian.

The intersection of the two lines will be at the astronomical observatory of San-Fernando.

Military Search-light.—According to *l'Electricien*, a system of electric illumination for fortresses has been adopted by the German military authorities. The intensity of the light is sufficient to illuminate objects within a radius of 12 kilometres. The apparatus, of which the details are kept a strict secret, though the essential novelty is stated to be in the use of parabolic mirrors, is constructed by Schuckert and Co., of Nurnberg. All the fortresses on the banks of the Rhine are to be immediately provided with the search-light in question.

Brussels Electric Tramway. The Julien accumulator appears to be giving very satisfactory results on the Brussels tramway. The total weight of each car, with its accumulators and its full complement of passengers, is 6,100 kilos; the weight of the batteries is 1,500 kilos; and the run, without changing the accumulators, is 48 kilometres, which, according to the Report of the Congress of Tramway Companies, might be increased to 55 kilometres. Two sets of accumulators are employed for each car; one being re-charged whilst the other is in use.

The Electric Light in Spain. The contract for the lighting of the boulevards at Barcelona was recently submitted to public tender. Only one firm, however, the *Sociedad Espanola de Electricidad*, came forward, its tender being accepted. The directors of the Commercial Union Circle, of Madrid, have applied for tenders for the installation of the electric light at their *hotel*. This is to comprise three arc lamps and from 160 to 200 incandescence lamps, with machinery to be located in a detached building. The contract will remain open until the 1st of March next.

Electric Light in a Glasgow Theatre.—Taking the lead in the west, the lessees of the Royalty Theatre Glasgow, some time ago decided to introduce the electric light for stage purposes. With this in view, an order was given to the Anglo-American Brush Light Company, and during the past week, under the supervision of Prof. Sir William Thomson, the work of construction was carried out. The light has not only been fitted up for stage uses, but it has also replaced the gas in every part of the auditorium and the accesses. The entire installation consists of over 300 lights.

An Electric Club.—The New York Electric Club was recently opened with considerable *éclat* at 17, East Twenty-second-street; on which occasion the members and visitors had the opportunity of listening to an address by Prof. Rowland, on "The Electrical and Magnetic Discoveries of Faraday." A letter was received from Prof. Sir W. Thomson, expressing his earnest wishes for the prosperity of the club, and his regret at being unable to hear his friend Prof. Rowland. The president is Mr. Henry C. Davis, and Messrs. G. W. Hebard, Thos. A. Edison, J. B. Powell, and G. L. Beetle, are vice-presidents.

The Electric Top.—This scientific toy, described by *La Nature*, is constructed of a disc of soft iron, mounted on a central "peg." When revolving with a certain velocity, the disc is repelled by the poles of a magnet; under other conditions, it is, of course, attracted. It is said to illustrate the production of induced currents in conductors moving in a magnetic field. It appears to us that this may be illustrated by the rapid diminution of the velocity of rotation; but that the *repulsion* illustrates more especially a preponderating effect of the inverse current induced in those portions of the conductor which are approaching the

magnet over that of the direct current induced in the metal moving from the poles.

The Khotinski Lamp. The incandescence lamp of a Russian inventor, M. de Khotinski, manufactured by him at Rotterdam, has for some months passed been introduced in France, being employed for several installations in Paris, notably those at the *Nouvel Opéra* and at the *Banque de France*. This lamp, of which the mode of manufacture is kept a profound secret, has, according to the *Bulletin International de l'Electricité*, a filament which is obtained from an American vegetable product, treated chemically prior to being subjected to a high temperature, and which is possessed of great homogeneity. The lamp however, does not appear to possess any very special qualities of duration or economy, its consumption per candle-power being 3.5 watts when an average life of 1,000 hours is required.

A New Metre. According to the system of measurement which M. Freycinet is seeking to introduce, in substitution for the C.G.S. system, the unit of length or metre is the acceleration produced by gravity in 1 sec. in a body falling freely, i.e., in *vacuo*, in the latitude of Paris. It would therefore be equal to 9.8 of the present metres. The unit of volume would be somewhat less than the *litre*, viz.: a cube of which the side measures $\frac{1}{100}$ of the new metre. We apprehend, and we must also say we hope, that the new system will not find favour amongst electricians. The unanimous adoption of the C.G.S. system by the International Congress of Electricians, under the presidency of M. Dumas, in September, 1881, may, we think, be regarded as final—at least for the next quarter of a century—supported as it is by the names of Sir W. Thomson in England, and of Helmholtz in Germany.

Weston-super-Mare.—According to a local paper, we learn that owing to the damaging statements made by Alderman Bruford and other shareholders in the Taunton Gas Company respecting the reliability of the electric light in that town, members of the Local Board and other gentlemen, who are desirous of seeing the electric light introduced into Weston, have privately visited Taunton upon several occasions during the past few weeks, to test the accuracy of Mr. Bruford's statements, with the result that they are unanimously of opinion that there is no justification for such statements, the light upon each occasion being in every respect equal to what it was when the deputation visited Taunton on November 18th, 1887. It has now been definitely decided to use only the system adopted in Taunton (the Thomson-Houston), in the event of the electric light being introduced into Weston super Mare.

"I Told You so."—We all know the story of the woman whose incessant remark was "I told you so," being made to say when her husband stated the brindle cow had swallowed the grindstone, "I told you so." The London correspondents of country papers fall into another error and "believe so" in every long drawn tale they hear about electricity. The correspondent generally writes: "I hear that Mr. So-and-so, a painter, or a tinker with an inherent tendency to dabble in electricity and mechanics, has made a startlingly simple discovery of an electrical application to cycles and bicycles, &c., and has sold the patent for £50,000. Happy man; though it would have been just as wise to have said £100,000 while about it. Why will not these absorptive correspondents imbibe a little of the most elementary information upon matters electrical, and they would then know that £50,000 was about as likely to be

said just now for an electrical patent as a tunnel is to be made to the Antipodes.

Brooklyn. The tenders for lighting the Brooklyn streets during 1888 show that the Citizens' Electric Company were charged 182,500dols. per lamp per year, the Municipal Electrical Electric Light Company the same sum, the Citizens, Metropolitan, People's and Nassau Gas Companies 22dols. per light per year. The Williamsburgh Gas Company charges 21.75dols., the Brooklyn 19 80. These prices are the same as last year, and under them it cost the city for lighting 388,925dols. The amount to be spent during the next year, or, rather the current year, is 180,000dols., and there is a balance in hand of 20,000dols., with which the electric light is going to be extended. The two electric companies, one in the Eastern district and the other in the Western, have offered to supply the city at 50 cents per night for each light, but the price is fixed at 30 cents per night for each light of 1,200 candle power, and 10 cents per night for each light of 2,000 candle power.

Brussels Exhibition.—Great dissatisfaction prevails amongst Belgian electric lighting firms by reason of the alleged action of the Executive Committee in placing the letting of the exhibition buildings in the hands of foreign companies. This dissatisfaction has been shown by the abstention of the firms in question from any participation in the undertaking. In a letter addressed to Count d'Anethout by "The Members of Committee 47" that for Electricity and its Applications—the writers say: "We have observed with great surprise that, with the exception of the *Société Industrielle d'Electricité*, no Belgian electric lighting firm has sent in any application for space." Finally, they request the Count to intervene in the matter, and to request the Executive Committee to adopt such measures as may allow of the Belgian electric lighting companies being represented in a manner befitting the importance that this industry has obtained in the country, and the continuous progress that is being achieved in it.

Lighting of a Yacht.—The steam yacht "Victoria" Capt. Lowisham, late of the "Ceylon", which sailed from Gravesend on the 11th inst. for a pleasure cruise of three months in the Mediterranean, has just been fitted with a new electric light plant by Messrs. Browett, Lindley, and Co., of Manchester. The plant consists of 150 incandescent lamps, and an F2 "Victoria" brush dynamo, driven direct at 200 revolutions by a new type of vertical tandem compound engine, recently patented by the above firm. The installation of the generating plant presented some difficulties, as the whole had to be carried on a wrought-iron platform erected for the purpose in a corner of the main engine room, and level with the top of the cylinders. The whole plant is very compact and entirely self-contained, and the engine is constructed to work either as a high pressure engine with 50lb. steam from the donkey boilers and exhausting into the air for use when in port, or to work compound with steam from the main boilers, which carry 80lb. pressure and exhausting into the main condensers.

Physical Society, Glasgow University.—An ordinary meeting of this society was held on Friday night, the 10th inst., Mr. Maclean, Pres., in the chair. Mr. Thomas Gray B.Sc., exhibited and described an improved apparatus for the determination of the intensity of the horizontal component of the earth's magnetic field. In this apparatus a magnetometer consisting of a small magnetic needle about 1cm. in length, mounted in a light aluminium frame carrying

a small mirror suspended in a vertical glass tube fixed to a wooden base plate, is supported on a light but rigid wooden frame which is capable of turning round a vertical axis. Two deflector magnets mounted on suitable stands are carried by a strip of thick glass, which turns round the same vertical axis in such a way that the deflectors are always on opposite sides and at equal distances from the magnetometer needle. The method is in principle the same as that of Gauss, and the apparatus is a more perfect form of that described by Mr. Gray in the *Phil. Mag.* for December, 1885, the *sine* method being adopted in this case instead of the *tangent* method as described in the paper just referred to.

Anglo-American Brush Company.—At the invitation of the directors of the Anglo-American Brush Electric Light Corporation, a party of gentlemen, including several members of the Commission of Sewers, on Saturday paid a visit to the works in the Belvedere-road, Lambeth. The guests were taken through the works and the various apparatus explained. Special attention was called to the Callender and Webber patent for laying down mains, by which a separate channel is provided for each cable. The passage is impervious to water or gas—indeed, at the works can now be seen a segment which is still practically as good as ever, although it has undergone the severe test of being covered with water and generally "misused" for a period of two years. By this system, moreover, the cables can be seen to and repaired, if need be, without the inconveniences necessarily entailed by the breaking up of a roadway. All the accessories of electric lighting used by the Brush Company are manufactured on the premises, giving employment to about 300 hands—men, women, and boys, the two latter finding employment in the glass-blowing and incandescent lamp departments.

M. Lucien Gaulard.—It is with sadness and sincere regret that we have to refer to the mental illness of this well-known electrician. We read in a French paper that on Saturday night a well-dressed man rang at the gates of the Elysee and ordered the *swisse* to show him immediately into the presence of the President of the Republic, as he had a communication to make to him which would admit of no delay. On being questioned, his condition became evident, as he asserted that he was the Supreme Being and would brook no delay. He was taken to the station at the *Rue d'Angon*, where he passed the night. On the following morning he was sent by the Commissary of Police to the infirmary of the *dépôt*, where he was examined by the celebrated *aliéniste*, Dr. Garnier. The impression previously produced as to his mental condition being fully confirmed by his extraordinary ravings and by an incipient general paralysis, it was decided to send him to the hospital of Sainte-Anne. M. Gaulard, who is best known by his work in connection with secondary transformers, but who is also the author of other important works, obtained the prize of 10,000f. at the Turin Electrical Exhibition, and was created by King Humbert Chevalier of the Order of Saints Maurice and Lazare.

Bradford Telephone Exchange.—The subscribers to the Telephone Exchange, invited by the National Telephone Company, Limited, had a private view of the new switch-room and switch-boards which were opened for use on Thursday. The system adopted is that patented by the Western Electric Company, of Chicago, and is known as the "multiple system." Its leading characteristic is that the wires are so arranged by an ingenious system of duplication that each operator has under her control not

only, as hitherto, the wires for which she herself is responsible, but also all the other wires connected to the Exchange. By the old method each operator had under her control fifty wires. Should any one of these fifty wires wish to communicate with one in a set in charge of another operator, it became necessary for the one operator to speak across the room to the other to make known the number wanted, and then the connection was made by means of trunk wires connecting the two sets. This system, whilst suitable for a small exchange, has been found quite inadequate to cope with the amount of business which now passes through the larger Exchanges. According to the new plan, each operator has arranged before her in blocks of 100, the whole of the 500 lines now connected to the switch room. It is only then necessary for the operator called to connect her telephone to the line of any subscriber asked for, to ascertain if it is at liberty, and if so to at once make the connection. It is obvious that a great saving of time must thus ensue. The multiple system has hitherto only been adopted in the London, Liverpool, and Glasgow Telephonic Exchanges.

Atlantic Cables. The *Financial News*, writing on this subject, says: "Like the southern railways, all the Atlantic cable companies are avowedly anxious for peace. The only thing they desire more is a remunerative tariff, and that is what they have greatest difficulty in agreeing about. Each company seems to have its own idea of what the new rate should be. The Anglo-American is in favour of a shilling tariff, Sir John Pender being of opinion that it would yield results very satisfactory to his shareholders. The Direct Cable Company would also prefer the shilling scale, at least as an experiment. Strange to say, the advocates of higher rates are to be found among the younger companies which came into existence in order to confer on us the blessings of cheap telegraphy. Mr. Jay Gould has signified his readiness to join in a general advance, but he has doubts about the efficacy of a shilling rate. His cables were so characteristically financed that they require a very large income to yield even a nominal return to their watered capital. Their actual cost to him was about 7,000,000dols.; he capitalised them at 14,000,000dols., and then leased them to the Western Union Company for fifty years on a guarantee of five per cent. per annum. The Western Union Company should therefore clear 700,000dols. per annum in order to avoid loss on its guarantee. At the sixpenny rate it must of course have been losing heavily, and Mr. Gould seems to be doubtful if even a shilling per word could enable it to cover its guarantee. So far as he is concerned there is no thought of less than a shilling per word being tried." With regard to the breakdown in the negotiations with Mr. Mackay the news requires a good deal of supplementary matter added to its explanation to make it even approximately correct.

Electric Lighting of the City Streets. At a special meetings of the Commissioners of Sewers, held at the Guildhall on Tuesday afternoon, under the chairmanship of Mr. W. H. Parnell, the Streets Committee submitted an amended report on the proposed contract between the Anglo-American Brush Electric Light Corporation and the Commissioners, in which it was stated that the committee had further considered the proposed arrangement with the Corporation, and that General Webber, the chairman of the Company, had agreed to deposit £1,000 to be forfeited in the event of the Company not commencing

their work within six months from the signing of the contract, or not completing the installation by October, 1889; and that in the event of the Commissioners seeing reason to terminate the contract for public lighting within seven years, the Company's exclusive right of way for private lighting should then cease. Mr. J. C. Bell (chairman of the Streets Committee) said he was prepared to at once go into the question. It seemed ridiculous to keep on adjourning so important a question from month to month, and he asked the court to bear in mind that unless the Company were permitted to at once commence their works, the lighting of the City by means of the electric light would not be accomplished by the winter of 1889, but would be thrown back until 1890. The Remembrancer, Mr. G. Prior Goldney, stated that it was of the most vital importance that some action should be taken with respect to the provisional order now before the Board of Trade at the instance of the South Metropolitan Electric Supply Association, as that association was seeking powers to light a portion of the west-end of the City, that being part of the area embraced in the contract proposed to be entered into with the Brush Company. Mr. Bell remarked that, after hearing what the Remembrancer had said, there was every reason for having the question decided at once, and for that purpose he would move that the matter of the electric lighting of the City be put on the paper of business for discussion at the commencement of the business of the court next Tuesday. This was agreed to.

Electric Boat.—We are informed by *Electrile* that a ship's boat or cutter, the motive power for which is supplied by accumulators, has just been constructed by the *Société des Forges et Chantiers de la Méditerranée* under the orders of the French Admiralty. The preliminary trials of this vessel made at Havre were, according to the reports published, entirely successful, and it has been assigned to the military port of Brest, there to be employed in ordinary work, in order that its behaviour and capabilities may be thoroughly studied. The boat in question is of the same dimensions as the steam cutters (*canots à vapeur*) hitherto built for the French marine, i.e., 8.85 metres in length, 2.25m. in breadth, and 1.54m. in depth. The latter vessels are of very heavy build, being intended for work in rough as well as in fine weather. Their speed is six knots an hour, which they are capable of maintaining during four hours with the quantity of coal and water that can be stored in them. The conditions laid down for the construction of the new vessel were that the regulation steam motor should be replaced weight for weight by an electric motor, and that the speed attainable by steam should be maintained for at least six, instead of four, hours. These conditions have been almost exactly carried into effect, although the weight of the electrical apparatus is slightly greater than that of the steam motor and its accessories. These, comprising the engine, the boiler, coal and water-tank, together weigh 2,850 kilos; whilst the electrical material necessary to obtain the propulsion during the required period, and consisting of the dynamo, the motor and reversing apparatus and the accumulators, weighs 2,891 kilos. Taking into account the great advantage of being able to continue the propulsion during six instead of four hours, the experiments at Havre must be regarded as being altogether in favour of the new vessel. The electric motor, constructed under the best conditions as regards lightness, was devised by Capt. Krebs, well-known through his experiments in military aerostation; it is provided with an apparatus to allow of the movement being rapidly reversed without shock. The

accumulators are on the Commelin-Desmazure system, and are composed of 132 couples, so arranged as to allow of the regulation of the speed by means of a commutator. This application of electricity, which is by no means a novel one, but which has not until recently been carried out in a practical form, would no doubt receive a rapid extension if the ratio of weight to power in secondary batteries could be considerably reduced.

The Meteorological Society.—At the meeting of this society on Wednesday the Hon. R. Abercromby read a paper on "Electrical and Meteorological Observations on the Peak of Teneriffe." The following are the author's remarks on the electrical portion of these observations:—All over the world the normal condition of the atmosphere has been found to be that of a greater or less positive potential between a point above the earth and the surface of the ground itself. The only notable exception to this was found in some observations made on the Peak of Teneriffe in the year 1856 with a gold leaf electrometer. Then it was noted that the condition of the Peak was constantly resinous or negative. Fifteen sets of observations were made—nine at Puerto d'Orotava, 50ft. above sea level, and six at various altitudes up to 12,200ft. Each set usually consisted of three series of—earth, air, earth—determinations. The height of the fuze may be taken at 5ft. 5in. Every observation showed positive electricity of variable potential. One of the Orotava sets had to be discarded. The mean of the remaining eight gave a positive potential of 138 volts, the highest being 193, the lowest 98 volts. One day, when an ascent was made to the rock of Gayga, an observation on the slope of the mountain at 3,800ft. gave a potential of 99 volts, while on the rock itself, 7,100ft., tension rose to 257 volts. Electrometer observations, Rock of Gayga (7,100ft.), October 20th, 1887, 12.50 p.m.:—

Earth	7.49	7.43	7.15
Air	5.96	6.15	6.17
Earth	7.43	7.33	7.45

The figures give the readings of the screw, not the potential in volts, but the $\frac{1}{100}$ th turn of the screw was practically equal to a difference in tension of 2 volts. A few days later the Peak was ascended. At 5,600ft. on the slope of the mountain the potential was 111 volts. On the top of the Peak, 12,200ft., the potential rose to no less than 549 volts. This was at 8 a.m. of October 24th. The wind was blowing at the rate of about ten miles an hour from the northeast, and was doubtless the north-east trade. No upper clouds were visible. The dry and wet bulbs marked 14deg and 26deg. respectively. There was a little white frost on the ground—pumice dust, sulphur, and whitened lava—and the earth readings were remarkably accordant, only differing by the $\frac{1}{100}$ th of a turn of the screw. One day at Orotava there was very heavy rain, and negative indications might possibly have been obtained; but the author did not think it expedient to let the electrometer be drenched. The results of all the observations point unmistakably to the conclusion that during the month of October the electrical conditions of the peak of Teneriffe were the same as in every other part of the world. The potential was moderately positive at the same distance from the ground even at considerable altitudes, but the tension rose remarkably round a sharp point, and a projecting edge of rock.

Factory Lighting.—Messrs. James Paterson and Co. have just had built a new factory at Dundee, called the

Lawside Factory, for the manufacture of jute. The main factory is 260ft. long by 132ft. broad. Adjoining this, but partitioned off by a main wall with sliding iron doors, are the finishing and forwarding departments, having a floorage space of 150ft. in length, by 90ft. in breadth. This factory will be lighted entirely by electricity, and it is the largest work in Dundee so lighted. A Mather and Platt dynamo is used, of the Manchester type, No. 6A size, compound wound for an output of 100 volts, 330 amperes at a speed of 900 revolutions per minute. The resistance of the shunt coils is 18 ohms, and of the series coils 0.0045 ohms, and of the armature 0.01 ohm, the total electrical efficiency being 94 per cent. The machine is fitted with copper commutator insulated with mica, and has three brushes on each rocking arm, each separately adjustable with spring forward thrust and hold-off catch. The dynamo is driven by the main factory engine from the second shafts, and generates the current necessary for 423 Edison-Swan lamps of 16, and a few of 8, 32, and 50 candle-power at present installed, but is sufficiently large to supply 550 lights. The current is controlled by a five-way switch placed in the dynamo, the five main departments being the factory, finishing department, handloom shop, engine room, and offices. The offices are lighted by 52 lamps controlled by an eight-way switch, so that any of the rooms may be lighted at pleasure. Each narrow loom is lighted by one of the lamps, the wider looms having two. Safety fuses are used throughout the installation. The wires are insulated, and besides are enclosed in a wooden casing so as to prevent, as far as possible, any damage arising. Provision is made against any accident to the new illuminant by nine Bower lamps placed at various points throughout the works, so that in case of the engine having to be stopped from any cause the gas lamps can be turned on in a moment. The electrical engineers who have carried out this work are Messrs. Lowdon Bros., and it has been carried out under the superintendence of Professor Ewing, who wrote out the specification, and has acted throughout as consulting engineer for the installation. The factory is a model one in many respects, and the firm has spared neither pains nor cost to provide a building in which they shall be able to carry out the work in the best possible manner. On Saturday night last the employees at the Lawside and Heathfield Works were entertained to tea and a dance by Messrs. Longair and Couper, to the number of about 800, in the yarn loft, which was decorated for the occasion. Whilst the party were assembling the loft was lighted by gas only; but after the guests had taken their seats the electric light flashed out from a large number of lamps hung from the roof, and instantly there was a brilliant illumination of the large room. A hearty cheer from the people showed their appreciation of the new light. In the course of the evening Mr. Longair, who, with Mr. Couper, are the partners of the firm, stated that they had tried to make the new works, with respect to ventilation and heating, as comfortable and healthy as possible; and with regard to electric lighting they had improved vastly on the present system. He thought that with certain precautions the electric light would certainly be the light of the future, as was evidenced by the brilliant effects produced in the works that evening. There is no doubt, we think, that the conclusions of Mr. Longair are correct, and that it only requires care and attention on the part of electric light engineers to vastly increase the business that is being done in the lighting of all kinds of factories.

CONSTANT PRESSURE IN ELECTRIC TOWN MAINS.

III.

Before entering upon the question of regulating the pressure by resistances, which is the third method mentioned in our last article, it may be useful to briefly recapitulate the investigation as far as it has been carried in our two previous articles. We showed, in the first place, that the variation of 5 per cent. in the pressure up and down from the standard, as contemplated originally in the Board of Trade Rules, is inadmissible, and that $1\frac{1}{2}$ per cent. would probably be found a practical working limit by which the size of mains must be determined. We then dealt with the economic conditions regulating the size of feeders as dependent upon the permissible loss of pressure, which, by way of example, we took at 20 volts. The next step in our investigation was to show how an increase in the number of feeders produces economy in copper, but that in that case the pressure on each feeder must be under independent control. The device of using lamps of different voltage we found to be impracticable, and we also found that the pressure on each feeding centre must be at all times kept at 101.5 volts if the lamps are of 100 volts. The difficulties of, and objections to, using an independent dynamo for each feeder, and those of using a number of main dynamos, and small regulating dynamos for the feeders, we found to be so great as to preclude either system from practical use, leaving available only the method of regulating by resistances, which we shall now examine in detail.

For reasons already stated, the resistance to be put in each feeder must be equally divided between the outgoing and incoming branch, and the pressure to be kept on the main bars at the station must evidently be at least as high as that required for the feeder which is most heavily loaded. The resistance on this feeder would then be completely cut out, and the resistances on the other feeders would be adjusted inversely to the current each has to carry. Let c_1, c_2, c_3 , &c., represent the currents in the first, second, third, and the other feeders, r_1, r_2, r_3 , &c., their resistances, and ρ_1, ρ_2, ρ_3 , &c., the resistances of their respective rheostats; then the following formulæ express the condition of regulation:

$$\begin{aligned} p &= 101.5 + c_1(r_1 + \rho_1) \\ &= 101.5 + c_2(r_2 + \rho_2) \\ &= 101.5 + c_3(r_3 + \rho_3). \end{aligned}$$

If the first feeder is the one most heavily loaded, we reduce ρ_1 to zero, and have the pressure on the main bars,

$$p = 101.5 + c_1 r_1.$$

The resistance to be inserted into the second feeder is found from the formula

$$c_1 r_1 = c_2(r_2 + \rho_2);$$

giving

$$\rho_2 = r_1 \frac{c_1}{c_2} - r_2.$$

The smaller c_2 , the current in the second feeder, as compared to c_1 , the current in the first feeder, the larger must be the artificial resistance ρ_2 to be inserted in the second feeder. If no current at all is required in the second feeder—that is to say, if all the lamps ordinarily supplied from

that feeding centre are switched out—the ratio $\frac{c_1}{c_2}$ becomes infinite, and the resistance ρ_2 must also be made infinite—that is to say, the connection of the second feeder with the main bars must be completely broken. There is no difficulty in doing this, but what happens if, instead of all the lamps on the second feeder being switched off, a few are left on? In this case the ratio $\frac{c_1}{c_2}$, although not infinite, is very large, and would require ρ_2 to be also very large. Now, artificial resistance coils, or rheostats, capable of carrying heavy currents, are always somewhat cumbersome; but when their resistance is required to be very high they become almost unwieldy, and the question arises whether our expedient of regulating the pressure by means of these rheostats is, after all, a practicable one, considering the large range of resistance required for each rheostat. To answer this question we must find out what is the smallest range of resistance we can do with in each rheostat. The

range naturally depends upon the more or less even use of light throughout the district, being greatest when the change in the density of lighting on neighbouring portions of the network is most abrupt. To obtain the limits we must, therefore, investigate some of the worst possible cases of unequal distribution. One of these cases is evidently when all the lights are on in the neighbourhood of alternate feeding centres, and no lights are on in the neighbourhood of the intermediate feeding centres. Another case is when the full demand and no demand alternate in neighbouring districts, each supplied by 2, 3, or more feeders. The first case is in its simplest form graphically represented by Fig. 1, where N N represents the network main (shown

FIG. 1.

by a single line, although in reality consisting of a pair of cables), and A B C D are the feeders, those shown in thick lines being supposed to serve the districts where the demand is at its maximum. We suppose all the lamps between a_1 and a_2 to be alight, all the lamps between a_2 and c_1 to be extinguished; and, again, all the lamps between c_1 and c_2 to be alight. For the sake of simplicity, we assume that the feeding centres are equidistant, and that all the feeders supply equal current when the demand is uniform. The problem is to find how much current flows through each feeder when the demand is uneven, as above explained. If the feeders B and D were disconnected, no current would flow in the portions of the main comprised between the points Bc_1 and Bc_2 , and the pressure at the points a_1, c_1 , and c_2 would be 98.5 volts. But the moment we connect the idle feeders, the pressure in B and D rises to 101.5 volts, and current flows from B to a_2 , from B to c_1 , and from D to c_1 , correspondingly diminishing the current in the feeders A and C. Lamps fixed up to a certain distance to the left of a_2 , and to the right of c_1 , will now be fed from the current in B, and the current from A and C will not reach so far as before. The point of lowest pressure on the main must evidently be that lying between the last lamp fed from A, and the next lamp which is already fed from B.

Let x be the distance in yards of the point of lowest pressure from A.

Let d be the distance in yards between A and B.

Let r be the resistance of the main out and home per yard run.

Let γ be the current taken from the main per yard run at full supply.

Let C_A be the current in A.

Let C_B be the current in B.

Then the following equations are self evident.

$$\frac{C_A}{2} = x\gamma \quad \frac{C_B}{2} = \left(\frac{d}{2} - x\right)\gamma.$$

The range of resistance on feeder B is determined by the ratio between C_A and C_B and to find this we must ascertain the distance, x , as given by the condition that the drop in pressure from A to M must be equal to that from B to M.

Since lamps are supplied all the way between A and M the loss, λ , is half that which would take place were the whole current flowing out from A to M and back from M to A. We have therefore

$$\lambda = \frac{1}{2} \frac{C_A}{2} x r.$$

Similarly the loss between a_1 and M is $\frac{1}{2} \frac{C_B}{2} \left(\frac{d}{2} - x\right) r$ to which must be added the loss between B and a_2 amounting to $\frac{C_B}{2} \cdot \frac{d}{2} r$. We have therefore

$$\lambda = \frac{C_B}{2} \left(\frac{d}{2} + \frac{1}{2} \left(\frac{d}{2} - x\right)\right) r.$$

By combining the two equations we have—

$$\frac{C_A}{C_B} r = \left(d + \frac{d}{2} - x \right).$$

But from the equations for the currents the ratio of C_A and

C_B is $\frac{x}{d-x}$, hence

$$x^2 = \left(\frac{d}{2} - x \right) \left(d + \frac{d}{2} - x \right) \\ x = \frac{3}{8} d.$$

The point M lies, therefore, three times as far from A as it lies from a_m and the feeder A must carry three times the current which the feeder B carries. The same ratio evidently applies to the other two feeders, the conditions being identical. We find thus that, even under these very unfavourable conditions of supply, the ratio between heavily and lightly loaded feeders is only 3 to 1, and the maximum resistance required in rheostat of, say, the second feeder is

$$r_2 = r_1 \cdot 3 - r_1.$$

If the resistance of different feeders were approximately equal, then the greatest range which any of the rheostats need have to meet the case of unequal distribution above assumed is only about twice that of the resistance of each feeder.

FIG. 2.

Now as to the other case of unequal distribution mentioned. If, as in Fig. 2, a pair of heavily loaded feeders is adjacent to a pair of lightly loaded ones, the current flows from B right and left towards a and b , but from C only to the left of b . Similarly the current from D flows only towards the right towards d , but not to the left, whilst the current from E flows right and left towards e and d . The point of lowest pressure must again lie $\frac{2}{3}$ of the distance between feeding centres to the right of B and to the left of E, but the current in the lightly loaded feeders will now be half what it was previously, whilst that in the heavily loaded feeders has slightly increased. It is now 57 per cent. of the full demand instead of 75 per cent. as before. The ratio $\frac{C_1}{C_2}$ is thus increased to

$$3 \times 2 \times \frac{87.5}{75} = 7.$$

With feeders of equal resistances, the greatest range of resistance of any rheostat would therefore be about six times the resistance of the feeder. A smaller range would suffice if we had assumed one of the lightly loaded feeders disconnected altogether. It might be made a rule in arranging the regulating switches that any feeder should be disconnected as soon as the current it carries has decreased to say 15 to 20 per cent. of the current in the heavily loaded feeders next to it; and in this case the range of each rheostat need only be from three to four times the resistance of its own feeder. This is not an excessively large range, and there will generally be no difficulty in finding room for the coils without crowding them so as to impair their cooling capacity.

If the reader has followed us so far he will have seen that the problem of maintaining an almost constant pressure on a main, even under greatly varying conditions of supply, is capable of an easy solution, and, as a matter of fact, has been solved in many American and Continental town installations in the manner we have here generally indicated. It is hardly necessary to point out that by the adoption of a multiple wire system the cost of mains can be slightly reduced, whilst the method of regulating the pressure at the feeding centres remains equally applicable. We have, however, left the more complicated systems of direct supply out of consideration, because the method of

regulation is the same in all cases; and as we only dealt with elementary principles, we considered it preferable to show the application to the most simple case of a two-wire system working at 100 volts. There remains yet to be considered the question of economy. What percentage of the total electrical energy developed at the station is wasted in heating the rheostats? This question can evidently only be answered when the conditions of supply in any given case are definitely known. We select as an example the first case of unequal distribution described above, in which full supply and no supply alternate in the immediate neighbourhood of adjacent feeding centres. We found that under these conditions neighbouring feeders carry alternately $\frac{3}{4}$ and $\frac{1}{4}$ of their full working current. If the full supply is on all over the district, each feeder carries the full working current and loses 20 volts. At $\frac{3}{4}$ current the loss is therefore 15 volts, and at $\frac{1}{4}$ current the loss is 5 volts. We would therefore keep 116.5 volts at the main bars in the station, and short-circuit the rheostats of the feeders which carry $\frac{3}{4}$ of the full current. We would also adjust the rheostats of the other feeders (those which carry $\frac{1}{4}$ of the full current) so as to absorb 10 volts. If 1,000 amperes are being sent out, 750 amperes would thus go straight to the feeders, and 250 would go to the feeders through the rheostats generating heat equivalent to 2,500 watts. This energy is lost. The total energy developed is 116,500 watts, and that actually supplied to the feeders is 116,500 - 2,500 = 114,000 watts. The efficiency of the regulating appliances is therefore $\frac{1,140}{1,165} = 97.8$ per cent.

This is an exceedingly high efficiency, and only obtainable if we at all times regulate the dynamos as to produce exactly the pressure required by the heavily-loaded feeders, but no more. In practice, however, it is found advisable to keep at the main bars a slightly larger pressure, so as to have a small margin of regulation on all the feeders, but even allowing another 5 per cent. of loss on this account, the efficiency of resistances as regulators must still be greater than that of separate regulating dynamos, which we have already condemned on account of complication.

PRACTICAL ELECTRICAL UNITS.

BY W. B. EBBON.

(Continued from page 80.)

12. *Electro-Mechanical Relations.*—Having defined the various units by which engineers estimate the work given to and obtained from dynamo machines, we have now to consider the relation which the mechanical and electrical sets of units respectively bear to each other. We have said that the work given to a machine is expressed in the form of a pressure into a distance, and the power in the form of a pressure into a velocity, while the work received from a machine is expressed by electric quantity into difference of potential, and power by current into difference of potential. The mechanical unit of work, the foot-pound, has its exact electrical equivalent in joules, while the mechanical unit rate of performing work, the horse-power, has its equivalent in watts. Much time and labour have been spent in determining these relations with accuracy, and the following figures give the results:—

Work	1 Foot-pound	=	1.356 Joules.
	1 Joule	=	.73725 Foot-pound.
Power	1 Horse-power	=	746 Watts.
	1 Watt	=	.0013405 Horse-power.

13. *Relation between Heat and Work.* Of the relation between heat and mechanical work the reader has doubtless some knowledge. A railway train brought to rest at the platform by the application of the brakes is a familiar example of this relation. Here the visible motion of the train is rapidly converted into invisible molecular motion, the energy given up taking ultimately the form of heat. The kinetic energy of the train is transformed into heat energy when the brakes are put down, a resistance being overcome through a space, and work being thus performed as a result of the transformation. In the case of electric lighting it is evident that the energy of the current is converted into

heat in the arc and incandescence lamps; but it is also true that a certain amount of heat is generated when a current flows through the most perfect conductor. There is invariably some work done by the current in passing and the heat generated is an exact measure of this work. In the case of water flowing through pipes there is always due to the friction a certain amount of work done, and the heat generated due to this cause is analogous to the heat generated in conductors by the passage of a current. The rise of temperature in conductors is oftentimes very slight, because their resistance being low the work done in them is small. But when indifferent conductors, such as German silver or platinoid, are employed, the heating becomes very apparent for the simple reason that a greater amount of work is done per foot of length in sending the current through them. Between the work done and the heat generated in conductors there is a perfectly definite relation which has been carefully determined. In England the unit of heat is the heat required to raise a pound of water from 0°C . to 1°C ., and if the energy of the electric current is employed to generate heat we require for the production of each heat unit 1898 joules.

14. *Electrical Measurement.*—It is not the intention to describe here the various forms of instruments by which the work obtained from dynamos may be measured, but a brief reference, with a hint here and there relative to their use, may be made. It has already been stated that what it is desired to measure most frequently is the current flowing at any moment, and not the quantity of electricity which has passed after a given time. Instruments designed to measure the current are termed ampere-meters or *ammeters*, and are of endless variety, but the merits and demerits of the various designs need not be discussed here. For their action they depend on the property of the current to deflect a magnetised needle, or on the mutual action of two or more coils traversed by the current, or on the attraction between iron cores and current-carrying solenoids. In such instruments there may be a part which is caused to move in opposition to a controlling force, and which takes up a position depending upon the current flowing; or the controlling force may be adjusted by the observer until the force produced by the current and tending to move part of the system is balanced. In the former kind the parts on the mutual action of which the measurement depends have different relative positions for each value of the current, in the latter kind they maintain always the same relative positions. The former may be termed indicating instruments, because they continuously indicate the currents flowing without interference of the attendant. By means of a pointer attached to the moveable part of the instrument the current flowing from moment to moment is indicated on a dial graduated in amperes. Instruments in which a moveable part is balanced by the torque of a spring or by weights are termed zero instruments, because the moveable part is always at zero when a reading is taken, the force tending to move it from zero being balanced first. In these instruments the torque of the spring or weight in the scalepan measures the current flowing, but they labour under the great disadvantage of requiring manipulation by the observer before readings can be taken. For this reason their use is restricted, being employed only in the laboratory, where in some forms they are most useful as standards, or in practical work under circumstances which leave the user no choice. Zero instruments, although mostly out of place in the electrical factory or in installation work, possess advantages as standards for the reason that the force tending to disturb the balance can generally be expressed by some simple law, if the parts preserve always the same relative positions. If, for example, there are two coils lying with their planes parallel to each other, in both of which a current of the same magnitude flows in the same direction, the attraction between these coils is discovered to be proportional to the square of the current. Having carefully ascertained by balancing one coil against a scalepan the attractive force corresponding to any particular current, we can tell at once, knowing the law which governs the instrument, the force corresponding to any other current. Similarly we know that in the case of two coils having their planes at right angles to each other, the tendency for one coil to twist round until its plane cor-

responds with that of the other coil is also proportional to the square of the current, and to keep the coil at right angles a torque or twisting force proportional to the square of the current must be put upon it. The construction of Sir W. Thomson's balance instruments, in which the attractive force of current-carrying coils is balanced by weights, is based on the law stated, as is also the construction of the well-known Siemens dynamometer, both good instruments for use as standards. To calibrate such standards we have recourse to the deposition of silver, and great care must be taken in making the determinations. The silver bath is placed in series with the instrument, and the current, which must be maintained constant, derived from a secondary battery. After a certain time the deposited metal is carefully weighed, the current flowing during the experiment having been

$$W = \frac{0.017253t}{\text{amperes}},$$

where W is the weight of silver deposited in grams, and t the time in seconds during which the experiment lasted. The result should be checked with currents of different magnitudes, and once having obtained the balancing forces corresponding to various currents, the instrument, being one not liable to alteration, and with a known law, can be employed for calibrating all kinds of ammeters for practical use.

For the measurement of differences of potential, *voltmeters* are employed which depend for their action on some of the properties of the current already mentioned, and the remarks made regarding ammeters, with respect to instruments employed for practical work and for laboratory use, apply equally to voltmeters. A voltmeter is really an ammeter of high resistance. It has its coils wound with a large number of turns of fine wire, instead of with a few turns of coarse wire, its resistance being often some millions of times greater than that of an ammeter. The current passing through it is consequently very small, its magnitude indicating the volts at the terminals. The terminals are connected by wires to the two points between which it is desired to measure the difference of potential, and the dial of the instrument is generally graduated in volts that the difference may be directly read off. In using voltmeters one must be careful to let the current flow through them only while a reading is being taken, in order that errors due to heating may be avoided. The current flowing through the instrument to indicate the volts depends only on its resistance, and if from heating the coils by the passage of the current the resistance increases, the readings obtained will obviously be lower than they should be. It is preferable to select for use as a standard a zero instrument, which, moreover, must not be liable to alteration with time. The standard may be calibrated by comparison with a cell of known E.M.F. in the following way. If we have a current flowing through a number of resistances we know from Ohm's law that the total difference of potential is to the total resistance as the difference of potential between any two points is to the resistance included between them. Suppose now we have a number of resistance coils, the values of which are known, connected in series with an unknown difference of potential, V , which may be produced by a secondary battery at the terminals of the set. To these terminals the standard voltmeter which is to be calibrated is connected, and our object is to find the value of V producing an indication on that instrument. Call R the total resistance of the coils. Connect the standard cell in series with a sensitive galvanometer and key, and let the two wires leading from these be connected up to embrace a part, r , of the resistance R . Knowing the direction of the current in R , let the cell be arranged so as to oppose any current which, due to the difference of potential between the ends of the wires, would be sent through the cell and galvanometer. Depress the key, and adjust r until no current flows. Then the difference of potential between the two wires is equal to the E.M.F. of the cell, and

$$V = \frac{ER}{r},$$

where E is the E.M.F. of the cell in volts. Care must be taken to make momentary contact only with the key, as a current through the cell when r is some way from adjustment is liable to polarise it, thus altering its E.M.F.

By taking several observations in this way the values of the indications throughout the whole scale of the instrument can be taken, but the resistance of the coils should be very high and the current very small in order to prevent errors arising from the heating of the coils.

(To be continued.)

EFFICIENCY TESTS OF ELECTRIC MOTORS FOR AMATEURS.*

BY W. F. D. CRANE.

My purpose in presenting this paper before the association is to describe clearly and briefly, for the benefit of those who as yet have but a limited knowledge of electricity, the methods and apparatus employed in the tests for determining the efficiency of an electric motor.

As is well known, any self-exciting dynamo can be used as an electric motor by reversing its function as a generator and supplying it with electrical energy to be converted into mechanical energy. Hence, it will be seen that the methods and apparatus described below are equally applicable for determining the efficiencies of dynamos as well as motors, with this distinction, however, that since the efficiency of any machine is the ratio of the power put into the machine and the useful work given out, in the case of a dynamo, we have to determine the ratio of the mechanical work expended in turning the armature to the electric energy produced. In a motor we wish to find just the reverse—that is, the ratio of the electric energy contained in the current supplied to the motor to the mechanical energy given out in useful work.

The losses occurring in both machines during the conversion of electrical into mechanical energy, and *vice versa*, are identical, and may be localized as follows:

1. Friction at the bearings; air friction, due to the rapid revolution of armature; and the friction of the brushes against the commutator.

2. Energy lost in the heating of the wires in armature and field coils; voltaic leakage, or leakage between the wires, and a certain loss due to self induction.

3. Magnetic leakage into the air and loss by the production of eddy or Foucault currents in the iron parts of the motor. These eddy or Foucault currents are useless currents which are set up in the iron in armature and field magnets by the mutual inductive effects of the magnetism of armature and field magnets and of the current passing in the armature.

The energy of a current can be expressed, provided we know the number of amperes and the number of volts of potential between the two ends of that part of the circuit in which the energy to be measured is being expended. The number of amperes is measured by a suitable ammeter, the number of volts by a suitable voltmeter. The product of the volts into the amperes expresses the electrical energy expended per second in terms of the unit of energy, denominated "watts." As one horse-power is equal to 746 watts, the number of volt-amperes (i.e. watts) must be divided by 746 to express the result in horse-power. But the current equals the E.M.F. divided by the resistance. Ohm's fundamental law, or, $E = CR$, and $E = \frac{W}{C}$. Hence it will be seen that, if we can determine any two of the three quantities E , C , and R , belonging to the armature, shunt, or main coil circuits, we can find the electrical horse power in that circuit.

For example, suppose we want to find the electrical horse power consumed in the armature of a motor or dynamo. We find its resistance R , when the machine is at rest, measure the current C passing through it when the machine is in motion, and by the above formula, CR , readily determine the number of watts consumed therein. Dividing by 746 gives us the horse power.

There are three efficiencies which we may test for in an electric motor, viz., the efficiency of conversion, the electrical efficiency and the commercial efficiency.

The efficiency of conversion is the ratio of the electrical energy supplied at the terminals to the power actually

obtainable at the armature shaft; and this should never be less than 90 per cent. in medium sized and large motors. The balance, or 10 per cent., would be the percentage of energy wasted in the losses enumerated in (2) and (3), and would include the percentage of loss due to defective construction and an ill-proportioning of parts composing the motor. Or, expressed in symbols,

$$E_c = \frac{w + f}{EC} \dots \dots \dots (1)$$

where w is the useful power given out, f the friction, both being expressed in watts, and EC the electric energy supplied, as measured at the terminals.

This formula shows the capacity of the motor for utilizing the energy of the current supplied, and its determination is useful in that it shows the proportion of the electrical defects, and also requires a determination of the loss from friction, which may lead to its economic reduction.

The *electrical efficiency* is the ratio of the external electrical energy to the total internal electrical energy; that is, to the total electrical energy consumed in armature, shunt or main coil circuit.

$$\text{Or, } E_e = \frac{K}{EC} \dots \dots \dots (2)$$

The *commercial efficiency* is the ratio of the external electrical energy applied to the useful work given off.

$$\text{Or, } E = \frac{w}{EC} \dots \dots \dots (3)$$

In measuring the mechanical power given off by a motor, or consumed by a dynamo, it is now almost

Dynamometer for Small Motors.

universal to employ the Brackett cradle. This, as shown in the accompanying diagram, consists of a firm bed and uprights, the tops of which support the cradle proper C resting on knife-edges E . The motor is accurately centered on this cradle, so that the axis of the armature passes through the points of support of the knife-edges. Counterbalancing weights W are so placed as to balance the weight of the motor M , scale pan P and dynamometer arm A projecting horizontally from knife-edges. A friction brake or suitable apparatus, connected by belt with the motor pulley, is placed vertically above or below for the purpose of consuming the power given off by the motor for various currents and at various speeds. In lieu of a suitable brake a dynamo may be used, with adjustable lamp or resistance loads. The revolutions are counted by means of a wheel and worm G inserted at the end of the armature spindle. A platinum point at B on the side of the wheel comes in contact with a spring or mercury cup at each revolution, thereby ringing a single stroke electric bell D . All external connections in testing small motors should be made in mercury, so as not to introduce errors which would otherwise arise if wires were led directly to the motor.

* Paper read before the Electrical Engineering Association of Cornell University, December 9, 1887.

The figure shows a wooden cradle designed for the testing of small motors not much over $\frac{1}{2}$ h.p. This cradle is built of well seasoned ash with a base 28 in. long, is one third as wide, and the supports are about 1 foot high. The supports are placed 19 $\frac{1}{2}$ inches apart, and carry on their tops grooved steel plates as bearing surfaces for the knife edges. The swinging cradle has an available platform 16 inches long by 6 inches wide. The knife edges are rigidly attached to nuts threaded upon the vertical iron bars supporting the counterbalancing weights. This permits of a limited adjustment of the cradle proper vertically in either direction, which adjustment, when made, is rendered secure by a lock-nut on the top of the cradle where the rod protrudes from the wood. When testing for such small powers it is especially necessary, for the sake of accuracy, that all extraneous friction or displacements should be avoided; hence all connections are made in floating mercury, as shown. The dynamometer arm is 30 centimetres long, and a short scale (not shown), projecting from the side of the support, serves to show when the cradle has reached its position of equilibrium, or zero point. In large cradles, designed for testing machines of several horse-power, the scale pan is replaced by a weight sliding on the dynamometer arm and the speed is taken by hand with an ordinary dial speed counter.

By this cradle arrangement the motor is virtually converted into its own dynamometer. The instant that it does work there is a reaction between the armature and field magnets which causes a displacement of the cradle. By placing weights in the pan, the dynamometer arm can be restored to its position when at rest; then the couple formed by the weight in the pan and dynamometer arm serves to balance the force of the reactions. By a determination of the speed at the same time, the power given off in foot-pounds per minute is expressed by the formula $w = 2\pi Pdn$, where P is the weight in the pan in pounds; d the length of the dynamometer arm in feet, and n the number of revolutions per minute. Dividing this by 33,000 gives us the horse-power.

Or this formula, when P is given in grammes and d in centimetres, gives w in gramme-centimetres, and must be divided by 7.6×10^6 to express w in horse-power; or, to express it in watts, it must be multiplied by 981×10^3 .

The current and potential measuring instruments are placed in the circuit as shown diagrammatically in the figure.

The friction may be readily determined by revolving the motor armature by another motor or suitable apparatus substituted in the place of the brake. Dynamometer readings at different speeds may then be taken, as before. The terminals must be open to avoid converting the motor by this reversion into a dynamo.

We have now all the terms necessary to find the efficiency of any electric motor. In practice, simultaneous readings are taken of the current E.M.F., speed and dynamometer.

The following table shows the tabulated results of tests for the commercial efficiency of a small series motor, such as is used for running sewing machines and other light machinery. The column under "Dyn." gives P in grammes:—

C.	K.	K. C.	Speed.	Dyn.	W.	Eff.	H. P.
10	8.75	85.5	1,440	154.5	41.14	.47	.055
10.5	10.45	109.7	1,920	150	53.25	.485	.071
10.5	12.07	126.73	2,400	140	63.13	.49	.084
10.07	13.87	139.74	3,240	126	75.49	.54	.09

To find the efficiency of conversion, we may take as an example the data of the first test, when the motor was running at a speed of 1,440 revolutions per minute, with a current of 10 amperes, and giving an output of 41.14 watts. The friction at the same speed was 8.3 watts. Substituting in (1) we have

$$\frac{w+f}{EC} = \frac{41.14+8.3}{87.5} = 57 \text{ per cent., nearly.}$$

The resistance of the armature was .2 ohm, and of that of field .28 ohm, a total of .48 ohm. Taking the same test when the current was 10 amperes, the total internal electrical energy consumed in armature and field coils would

be $C^2 R = 10^2 \times .48 = 48$ watts. We then have for the electrical efficiency, by substituting in (2),

$$\frac{K}{EC} = \frac{48}{87.5} = 55 \text{ per cent., nearly.}$$

Though the cradle above described is built on a plan of lightness and of a size for the accommodation of motors of less than one-quarter horse-power, it will serve as an illustration of the cradle enlarged and constructed wholly of metal for the testing of motors of many horse-power. There are many dynamometer methods, and several modifications of the Prony brake, which have been used with more or less accuracy for determining the power given off by a motor; but the Brackett cradle has the great advantage of permitting of very delicate adjustment, and ease and accuracy of dynamometer readings. Its disadvantage consists in the time and excessive care necessary in the mounting of the motor and making of all adjustments, which make it an instrument more suitable for the laboratory than the practical requirements of the workshop. *Electrical World.*

JUVENILE LECTURES.

The second of this course of lectures on "The Application of Electricity to Lighting and Working" was delivered at the Society of Arts on January 11th, 1888, by Mr. W. H. Preece, F.R.S., from which we abstract the following:—

Last Wednesday I had the pleasure of showing you how electricity was employed to produce heat, and how, by means of the heat resulting from the passage of electric currents, we obtained light. To-night I intend taking you in a different direction altogether. I want to disabuse your minds of the idea that electricity is a prime mover in the sense we generally consider prime movers to be. It is nothing of the sort; it is simply an agent or a medium by which energy, such as I showed and described to you last Wednesday, can be passed through one of its stages. The first form of energy that I am going to call your attention to to-night is of the character generally called work. It means something done; objects moved, resistance overcome.

In all these actions of electricity that I am going to show you if an electric current, for instance, moves a magnet, a magnet moved will produce electricity; if an electric current, as I showed you last Wednesday, produces heat, heat in its turn will produce electricity, and so we pass throughout the whole range of mechanics and of sciences this principle of reversibility introduced. For another instance: suppose we compress air or gas, the gas always reverses the action, and exercises a reaction precisely equal in amount to the action that caused the compression. Take a letter weight. If you want to weigh a letter you do so simply by compressing a spring, and the weight of the letter is measured by the reverse action of the spring in pressing the letter upwards. If you take a weight and lift it, wherever it may be, that weight is in a position to produce the reverse action. If we take two magnets or two currents of electricity and forcibly separate them, there is also always this reaction between them.

I want, in the first place, to show you what is meant by a magnetic field. We have now on the screen the projection of a steel magnet, it has been charged with magnetism, and as Mr. Carpenter now scatters over a glass placed above that magnet some very fine iron filings, you see that they arrange themselves in straight lines and curves, and when the glass is gently tapped these lines all arrange themselves in a radial fashion, with beautiful symmetry, in the most wonderful way, every particle being directed by attraction towards the pole; one pole the magnet only can now be seen, though, of course, every magnet has two poles. From that I want you to see by those lines picture to us the conditions of the space that surrounds every magnet, and in every single experiment that I am going to show you to-night the currents that we obtain are currents due to the fact that we can force conductors to pass through what is called a magnetic field, the neighbourhood of a magnet, such as you saw just now on the screen, is called a magnetic field. Whenever a

copper conductor, such as the wire I now have in my hand, or a wire arranged in other forms, is caused to pass through a magnetic field, it becomes electrified—it acquires that condition which enables us to obtain currents, and to use these currents.

I will now show you that we can utilise currents produced by this hand dynamo to attract and repel particles of iron. You now see on the screen two poles of an electro magnet; the difference between a permanent magnet and an electro magnet is that the one is made of steel and the other of soft iron. The permanent steel magnet acquires and retains its magnetism for a long time, whereas in an electromagnet the magnetism only exists during the time that a current is passing round the soft iron core. The picture shows the two coils of copper wire which, with their cores, form the electromagnet. Mr. Carpenter places some iron filings on that magnet, and on raising it they simply fall off, because there is no power present to attract them; I now cause a current to pass, and the iron filings being presented they are attracted, and continue so as long as the current is passing. The moment the current ceases the filings fall. That experiment failed at first, because a loose connection of one of the wires had been made, and no current passed. Faraday once made a remark that an experiment never failed. He said, "An experiment never fails, something happens that requires further investigation." In that experiment we have seen one of the simplest and most interesting elementary experiments in electricity. You have now seen that in a magnetic field we have the production of certain lines of magnetic force, and that currents of electricity produce magnetic fields. I want now to show you that whenever a conductor is passed through a magnetic field, work is done upon that conductor, it receives a kind of reaction, currents of electricity are produced. Similarly, if the conductor be placed in the magnetic field and a current from another source be passed through it, it is urged to move in a certain direction.

The fact that I want you to understand is, that whenever we pass a current of electricity through a conductor in the neighbourhood of a magnet, or in a magnetic field, it has a tendency to be moved or to rotate around that field in a definite direction. Here I have a horseshoe magnet; it is surrounded by a cage of copper wire, and through that cage I will cause a current of electricity to flow. You now see that the coils are rattling round at a rapid rate. I take the current off, and they stop; I put the current on again, and away they go. There you have an illustration of the fact that whenever you have a conductor in a magnetic field, and the conductor is traversed by a current of electricity, it is always urged to move.

I ought to point out to you that here we have the basis of every single experiment I am going to show you to-night. A current of electricity produced rotation, as you saw in that cage, and in this particular form that I want to show you on the screen you will see that rotation is produced in another way. You now see the apparatus on the screen. On the left and right hand side there are two upright columns, the poles of the magnet, exactly similar to the one I showed you on the table. Between those two poles there is an iron armature rotating on a centre point, and that armature is enveloped at each end by a small coil of copper wire. When a current of electricity passes through that copper wire it magnetises the iron bar, and the iron bar gets attracted and repelled by the two poles of the magnet, so that on my now putting the current on, you see, away it goes. The application of that principle has been carried out in the little apparatus I have here, called Froment's motor. This particular Froment's motor is used to wind a clock; in fact, it has only just been taken from a clock which, at twenty minutes past every hour, was wound up by a current of electricity actuating this motor. By its means the hand winding of clocks is dispensed with, and, supposing a battery will last for years, so the clock will keep time for years without one being troubled by the necessity of going round the house and winding up the clocks.

I will now show you how electric currents can be used to produce rotation or to produce motion. The history of motors is extremely interesting; it commences in the year

1823, when Mr. Barlow, the father of the present well-known engineer, the engineer of the Tay Bridge, and past President of the Institution of Civil Engineers, showed how it was possible to produce rotation by means of currents of electricity. The great apostle of electricity, Faraday, in 1831, did the same thing; and in 1833 Ritchie produced that very instrument that I showed you; but as far back as 1839 there was a Scotch gentleman of the name of Davidson, who thought that this principle was applicable to the drawing of trains on railways, and I have a slide, which Mr. Carpenter will now throw upon the screen, showing his locomotive.

You now see a picture of that machine, as used on the Edinburgh and Glasgow Railway, or rather, I will not say it was used, because I do not think it could have been used, but it was tried on that railway as far back as 1842. You see there were eight electro magnets, through which currents were passed, and these rotated the wheels. The machine worked at the rate of 9 miles an hour. Other distinguished scientists have worked in this direction. Jacobi, of St. Petersburg, about the same time, drove a boat on the River Neva by means of an apparatus very similar to Davidson's. Froment, whose apparatus I showed you, applied this principle to his workshops in Paris; the tools in his shop were worked by an exactly similar motor to that which I showed you just now. Motors are innumerable; I have on the table here models of various patterns. Mr. Immisch has distinguished himself very much in this direction, as has Mr. Parker and others. I want to illustrate to you the property that the electric current has of transferring power from one place to another. We can produce power in this room, and we could, without difficulty, transfer the power produced here to Liverpool, to Edinburgh, or even to New York; there is absolutely no difficulty whatever in transferring from this very room energy produced by means of the dynamo machine, and sending it, if you like, to Kamtchatka. Of course, the amount of energy you are able to transmit is quite another question, the amount varies very much with distance. Telegraphy is entirely dependent on the power which electricity gives us to reproduce mechanical effects at a distance. By this power we are able, in telegraphy, to transmit signals to any distance we like. This power is used for winding clocks, and for a great many practical purposes.

There is a friend of mine near East Grinstead, Sir Francis Truscott, who has his house fitted with electricity. He used to employ two men every day in raising water from a depth of 150ft. to fill his tanks, but when he had secured the use of electricity for lighting his house, I suggested to him that he might just as well use it for raising his water. It was no sooner suggested than acted upon. A little motor, not much larger than that you just saw, works for two hours a day, and supplies a full quantity of water for the house, and the services of the two men were dispensed with in that respect. There is no reason on earth why those people in the country who depend upon manual labour for the raising of water cannot raise their water with greater speed and more efficiency by means of an electro motor; in fact, this is carried out to a very large extent in South Wales by Mr. Brain. In the collieries in the Forest of Dean electro motors are used to a very large extent to raise water from depths of hundreds of yards, and through distances that approach from a mile to two miles. Well, the same power exactly that can be used to raise water can be used for many other purposes.

The present Prime Minister of England is a very advanced electrician. There is no man in England who has applied electricity so much for domestic and useful purposes as Lord Salisbury has at Hatfield. He was one of the earliest in the field; he has at Hatfield currents of electricity which are not only used for pumping but also for chaff cutting, turnip cutting, for sawing timber, and for many other farming and domestic purposes.

To-night I am also able to show you this operation of sawing by electricity. Sawing in country houses like Lord Salisbury's is required for cutting up the timber used for fires and for many other purposes, and here we have, by means of this motor, the counter-shaft and the circular saw at work.

(To be continued.)

THE ELECTRICAL ENGINEER.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 we gave a Portrait of F. GRAVES, Esq., President of the Society of Telegraph Engineers, and stated our intention of giving a series of Portraits of eminent Electricians of the century. In fulfilment of our promise we have already issued a Portrait of W. H. WOLLASTON, M.D., F.R.S., who was in his scientific prime at the beginning of the century. This will be followed by SIR HUMPHREY DAVY, F.R.S., whose fame as an electrician is still more prominent than that of WOLLASTON. Portraits of Past Presidents of the Society are in preparation, and we hope soon to have ready that of PROF. D. E. HUGHES, F.R.S.

THE CITY FATHERS.

Does any one read Ruskin now-a-days, or anything besides the daily paper? In lecture VII., "Ethics of the Dust," the lecturer, asked by the children to tell them about virtue, bluntly says: "I'm tired, and cross, and I won't," but for all that the delightful dialogue goes on to the students' edification if not to the children's. Surely the "City Fathers," in the shape of the Commissioners of Sewers, must be tired, or cross, or won't, say the final words that will enable one more firm step in advance to be taken with regard to electric lighting. According to the latest advices, however, the dialogue will be concluded next Tuesday, and then we shall know the result of several years' negotiations. Meanwhile, as the Chaldee manuscript has it, chap. iv., v. 14, "the man which is crafty began to take courage when his friends were gathered unto him, and he took his trumpet with boldness, and began to blow for them over which he had power." Which dark saying might be variously interpreted, as one has it, "the reference is to a cutish man who in other days flourished for a season, while for a season he followed the plan of 'Brer rabbit' and 'lay low,' till by-and-bye the opportunity came to trade upon the confiding public over whom the power of many words prevailed to their ultimate annoyance and loss."

It is useless to hide our meaning under the verbiage of old books, principally because so few have time to study ancient literature or to understand the allusions made therein. Delay on the part of the "City Fathers" is leading to difficulties. We will not argue that London should have the electric light; that would be useless—it is admitted. It is well known that the Brush Company have for a long time been negotiating with a view to carry out the work, and it is as well known that the contracting parties are virtually agreed. All that remains is to say the final "yea." The lingering over this "yea" has permitted two more Richmonds to enter the field. The Brush Company, as we say, has practically agreed with the Corporation, to light certain districts, with certain powers granted to them and conditions attached thereto. These powers and conditions are principally interesting to the contracting parties, and not to outsiders. The South Metropolitan Electric Supply Association is promoting a provisional order which, if granted, gives the Company certain powers over a portion of the area already, so to speak, filled by the Brush Company. Further, there jumps up a third company, who will seemingly go anywhere and do anything provided some fifty householders will take two thousand lamps. Unless there is a good deal more self denial exhibited than is usually the case in company working, we foresee some bitter antagonism, even if not costly litigation. Three rival companies working in one street will neither do good to themselves nor to the industry.

they represent. The misfortune in this particular case is that one company is thought to favour an underground system of distribution, another an overhead system, and the third whatever chance may throw in its way, so that the sole right possessed by one to take up the streets would not interfere with the wayleaves of the others. If any suggestion would find favour in the eyes of conflicting interests, it would be well if the South Metropolitan would consider the advisability of restricting the area desired, to something altogether outside that under consideration by the Brush Company, and that the House-to-House Company again should confine its efforts to districts outside either the South Metropolitan or the Brush. It may be said that our views are in favour of monopoly; so they are "a question of brooks and such like"—in other words our views are that success in central station lighting necessitates a kind of monopoly. One company, having selected its district, should be free from the competition of any other company, unless obviously unable to carry out the proposed work, then its position would simply be that of the dog in the manger, and the sooner a strong hand turned it out the better. The Brush Company was first in the field, it is able and willing to do the work, and only waiting the sanction of the Corporation. It may be the South Metropolitan is just as able and willing, but in the overlapping area they were not the first in the field, and should therefore retire. The competition of the House-to-House Company cannot be taken seriously. Companies desirous of doing work do not make their desires known through the advertisement columns of financial papers; but on the other hand such a method of procedure is just what one would expect of a company whose principal basis of work savoured somewhat of the speculative kind. London prides itself upon being the first city in the world, but in many ways it should be classified lower down, and especially is this the case in accepting improvements. Berlin, Vienna, New York, Paris, Brussels, have all more consistently adopted the new light than London, yet the benefit, if the light were adopted in the latter, would be incalculable. We do not advocate the light as a luxury; we contend it is almost a necessity. The work carried on in our busiest thoroughfares would be carried out more expeditiously, and at much less cost and inconvenience if there were more light. Neither the initial cost, nor the cost of maintenance are the sole questions to be considered in obtaining more light, and we trust next Tuesday will bring the final settlement of the matter, so that the work may at once be proceeded with, and London the sooner put upon a better footing so far as the lighting of its streets is concerned. There is plenty of room in the modern Babylon for several companies to work harmoniously, and every effort should be made not to

rush into disastrous competition to obtain a footing in any particular district.

THE PARIS EXHIBITION OF 1889.

Although we are unable to give a detailed report of the proceedings at the preliminary meeting of possible exhibitors held at the rooms of the Society of Telegraph Engineers on Monday last—as that meeting was scarcely of a public character—we may be permitted to refer broadly to the work being carried out.

The experience gained by the Society during the Exhibition of 1881, if for no other reason, makes it the best medium for organising that of 1889, and it may now be taken for granted that the Society will undertake the onerous and heavy duties involved in such organisation. A considerable number of the best-known firms engaged in the industry have been approached by Mr. Aylmer, and many have definitely stated their intention to exhibit. The days are young yet, and though Mr. Aylmer is possessed of a large amount of energy, many firms must necessarily be left to be dealt with by circular. Probably one of the first acts of the Society will be to issue a circular to all engaged in the industry. It has, we believe, been suggested that the society should act in 1889 as it did in 1881 in the matter of common expenditure by the exhibitors, that is, the expenditure for decoration, cleaning, for laying pathways, receiving and expediting parcels, etc. A guarantee fund was subscribed in 1881, but so great was the economy of a single instead of a multitude of paymasters, that the larger part of the fund was not required. The best way to provide for such common expenditure is for each exhibitor to contribute a *pro rata* sum according to the number of square metres he requires. It must not be forgotten by exhibitors in applying for space that if their exhibits will cover say x square metres they really require from 50 to 100 per cent. more space for pathways around these exhibits. A rough estimate of such expenditure would give 30s. per square metre as a minimum and 60s. as a maximum. This is altogether outside of personal payments, though as a matter of fact it decreases the personal expenditure by a larger amount than is paid into the collective fund—in that it is more cheaply to do the work collectively than individually.

TAUNTON.

One of the healthiest signs in the history of electric lighting is found in the first annual report of the Taunton Company. This Company, it is true, has had many advantages. It has not been heavily handicapped by promoters; nor has it paid fabulous sums for patents. It is really a local company, formed by local men, with local money to do local

work. This is as it should be, and if more companies are founded upon these lines, the greater will be the success of electric lighting. Of course the installation is but a little affair after all, yet it shows conclusively what can be done when working on a firm foundation. Two or three things have contributed to the success at Taunton. In the first place Mr. Massingham believed in the light and in himself. As a private individual, in a private adventure, he had to make it pay, and when the work grew beyond his control, he was satisfied with a moderate return. In the next place the arc-system adopted is one of the best, and it is exploited by one of the most conscientious firms at present doing business in England, whose work, so far as we know it, has been found to be thoroughly trustworthy. Lastly, the Company seems to have obtained an earnest, hardworking and capable electrician. Just as at Brighton, success has been due more to the personal efforts of Mr. Wright; so at Taunton, Mr. Massingham's labours have been admirably seconded by his electrician. Numbers of towns are hankering after the electric light, and we trust many will follow the example set them by Taunton. Make the work of local interest, carry it out with local capital, and the most pessimistic prophet will be compelled to say "All will be well."

THE TARIFF WAR.

(Communicated.)

The report of the proceedings at the meeting of the Anglo-American Telegraph Company has just been published. It is very amusing to see that what the shareholders call a "fighting rate," and what has been universally regarded as such, should be now spoken of by their Board of Directors as a "trial" rate, after doing their best to strangle the Commercial Cable Company when in the interests of the cabling public that company lowered the tariff for messages between the two Continents. The pool as good as acknowledge their inability to accomplish their purpose by entirely changing front, insisting that the present 6d. rate is maintained as a "trial," when in reality it was introduced, upon their own showing, for quite another purpose, viz., when they stated, in so many words, that if the Commercial Company would not agree to charge 60 cents a word they would wipe them out by reducing the rate to 12 cents a word. This was, indeed, endorsed by Mr. Pender at the Direct Company's meeting in January, 1887, when he is reported to have said that "the only way to ruin the Commercial Cable Company is to adopt a low rate." This is a trial rate indeed, but only too evidently not introduced for the object of testing its practicality, but solely for extinguishing the Mackay Bennett combination.

It is worthy of remark also that the only sensible utterance at the Anglo meeting was made by one of its own shareholders. "Why, it is contemptible," said that gentleman, "at this age of commercial civilisation, to talk about a monopoly in any business. The bottom of the Atlantic is no man's property, and it is open to all. It is infatuation to demand such a result. His lordship declared in this room that the 6d. rate was *not* to 'crush competition.' Mr. Newton says you must crush opposition. Crush Mr. Mackay! Yes. I should like to see you do it!" (Laughter.) Evidently no satisfactory reply could be made to this suggestive statement, as none was forthcoming. The great increase in traffic, of which the Board boasted, took place during the time the Commercial Cable Company adopted the shilling rate. It was as impractical

cable as it was absurd to pretend to base a policy when the conditions were so unfavourable; for further increase could hardly be maintained when the Commercial, for reasons to be stated, adopted the pool's 6d. rate. The result was inevitable, and should have been evident to the meanest comprehension, but the pool made a huge mistake when they thought that the 12 per cent. rate would have the effect of isolating and crushing the Commercial Company. It was thought that the single independent company would stand no chance against the united strength of the monopoly, but the facts of the situation have been intelligently grasped by merchants and others, and instead of succumbing to the enemy and crying for mercy, it seems by overtures made to Mr. Mackay that the enemy would be only too willing to come to terms of a very different character to those at first demanded.

The action of the Commercial Cable Company compares favourably with that of their opponents. That Company was established by honest and wealthy men, who, disdaining the watering of its stock, and not afraid of spending money, were nevertheless undesirous of ruining or attempting to ruin the pool. There was room for an independent company, and Mr. Mackay and Mr. Bennett threw themselves into the breach with the intention of getting a share of the traffic by means of a fair and just competition. The public who hate monopoly heartily co-operated and supported very fully that free and independent service. If the Commercial had been originated by schemers, started with a view of crushing the pool, or with the desire of being bought off at an advance price, the promoters surely would have started business at 6d., instead of which they simply reduced the then existing rate of 2s. by a trifling 1d. The public expected this reduction just as they expect the adoption of a permanent 1s. rate in the near future. Indeed, the Commercial Company was founded upon the express understanding that all profits over a certain margin, which would permit of a 5 per cent. or 6 per cent. profit on the capital outlay, should be devoted to the further reduction of the tariff. At the 1s. 8d. rate the receipts of the pool averaged £2,000 a day, whereas now they were making only £800 during the same time. After a fifteen months' trial of the 1s. 8d. rate, they announced that that rate was not, to them, sufficiently remunerative on their £12,000,000 of watered capital, and consequently they proposed to the Commercial Company a 60 cent per word rate, or else a threatened utter destruction at 12 cents. The first proposal was emphatically refused, and the pool began the fight by reducing the rate to 6d. Well, now the Commercial might have been expected to follow suit, but as they wished to prove to the public that not only were they not responsible for the fight, but were also opposed to a rate which scarcely paid expenses, and which was therefore prejudicial alike to the best interests of the promoters and shareholders, they met the 6d. drop by reducing their rate for the time being to 1s., and promised that as long as they were supported they would never exceed the 1s. 8d. rate. The 1s. rate was maintained by the Commercial Company for 16 months, when their customers expressed their friendly opinion that the difference in the two rates was so great, and that the fight had been so unequal and protracted, that they felt it was high time to adopt the 6d. rate also. This request was acceded to by the Company, but it cannot be too often reiterated that the advocates of the higher tariff, which was resisted by the Commercial, were the very first to introduce the 6d. rate, and, that being so, they will have to bear the consequences and pay for it.

One of the shareholders at the Anglo meeting found a solution to the question—"The longest purse will bring the others to terms." This is in a nutshell what the Board calls a "trial" of the 6d. rate.

The telegraphing public that have used the Commercial Company's cables speak exceedingly well of the service, and from what we hear it is doubtful if the pooling companies will so easily arrange rates as is expected. If the Commercial Company do not hurry the raising of the rates, it will be a poor look out for shareholders in the other companies, and it will be interesting to notice how much longer they will be prepared to support directors in a policy which, so far, has led to nothing but disaster.

CORRESPONDENCE.

EARLY TELEGRAPHY.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: In a note at page 122 you ask who can give any information about the telegraph scheme of the South Eastern Railway Company constructed in 1847? This was a double needle system erected by Cooke, the late C. V. Walker being his assistant and remaining in charge until his death in 1882. Walker wrote a charming little book called *Electric Telegraph Manipulation*, which was published in 1850, and is well worth reading. — Yours, &c.,

W. H. PREECE.

WATTS-HEURES OR WATTS HEURE.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: According to the rules for forming the plural of compound words, the first is the right form, for we have *basses tailles*, *plank-chants*, *chefs-lieux*, *choux fleurs*, &c., but then there are exceptions, such as *cheval-légers*, *grand-mères*, *appui-main*, *bec-signes*, and so on. The exceptions seem to be almost as numerous as the cases in which the rule is followed. *Moral*: Please yourself. Yours, &c.,

R. B. P.

THE INSTITUTE OF ELECTRICAL ENGINEERS.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: As reform is the order of the day, may I venture to propose some slight alterations in the procedure of the Institute that, I venture to think, would add considerably to the value of its discussions.

In the first place, I would ask if it is not possible to arrange that proof copies of papers to be read shall be in the hands of members a few days at least before the meeting at which they are to be discussed? I take it that the discussion of papers forms quite as valuable a part of the Institute as the reading of them; in fact, in many cases the discussion is of far greater importance than the paper itself.

I take it, too, that it is practically impossible, except in special cases, for men to give their best thoughts in their best form in a discussion immediately following the reading of a paper they only then make acquaintance with. Everyone who has attended the reading of a paper knows that it is often exceedingly difficult to follow the paper through, much less to discuss it immediately after. The author's wording, though clear to himself, often requires some thought on the part of a reader before he thoroughly grasps the author's ideas; and if this is so, how can it be possible rightly to understand what he hears read for the first time, and not by the author. Other institutes arrange, in some form or other, that members can, if they choose, have copies of the paper beforehand; and I venture to think that the result of that wise provision is to very greatly enhance the value of their discussions. If anyone doubts the point I have raised, let him compare the discussions when papers have been adjourned to the next meeting, proofs meanwhile being in the hands of members, with those taken on the same evening immediately following the reading.

I am aware that the Council have in many cases experienced considerable difficulty in arranging for discussions of papers, not on the same evening that they have been read, on account of the time at their disposal; and I therefore welcome the suggestion that was thrown out in your columns of an increased number of meetings. Why not meet every week if there are sufficient papers to fill up the time and allow every paper to be thoroughly discussed. Another point on which I venture to offer a suggestion is the length of time allotted to individual speakers. I take it again that in a discussion we want as many minds as possible to give us their ideas upon the subject in hand, and that the Institute is hardly fulfilling its functions if the same members monopolise the whole of the available time at each meeting.

As the whole time of the meeting only amounts to two hours, out of which at least from fifteen to thirty minutes is

unavoidably taken up with routine work, &c., it follows that, if one member speaks for an hour, the time left for others is very small indeed; yet I understand that it is a very common thing for a member after speaking say for twenty minutes to look at the clock, observe that he will not detain the meeting, as he knows there are others to follow, and go merrily on for another twenty minutes or more. I am aware that there must be considerable difficulty in dealing with this matter. Frequently a carefully prepared speech by an expert is of far more value than the paper itself; but again, I think it will be found that if some limit could be imposed, much padding might be avoided, and members would gradually learn the very valuable art of condensing their thoughts.

I would suggest, therefore, that it be within the discretion of the chairman to call the attention of the member who may be speaking, should he overstep a certain time limit, with the appearance of going on for still some time longer. Of course, in cases of this kind everything must depend on the tact of the chairman. Nothing is easier than to scatter the ideas of a speaker, especially if he be a nervous man, by an interruption; and it may often appear as though a chairman bore a grudge against a particular member if he should happen to have to call him to order very often. I think, however, that the matter may be safely left in the hands of the chairman. Further, I would suggest that no barefaced advertisements should be allowed under cover of discussion. A man's own experience, or his own thoughts, contributed for the benefit of himself and others, do good, and tend to the usefulness of the Institute; but a statement that he is the maker of so-and-so, or someone else is the maker and his things are the best, unaccompanied by any real information that can forward the aim of the Institute, viz., the instruction of its members, should be strictly tabooed. I would also suggest that country members, when unable to attend, should be allowed and encouraged to send their remarks to the secretary, to be read at the meeting, or inserted in the transactions, as may be convenient.

I would also propose, for the consideration of the Council and the members generally, a measure that may possibly appear, at the first blush, somewhat revolutionary, viz., that ladies should be admitted to our meetings, and as members of the Institute.

It is well known that there are numbers of female workers in the electrical field, to many of whom I imagine attendance at our meetings would be a privilege and a boon, while the possession of our transactions would be to a large extent as valuable to them as to us. Electrical science is so many-sided, and presents so many openings for female labour of every grade, that I feel sure increasing numbers of the opposite sex will find in it congenial and lucrative employment; and I think it can hardly be questioned that, if our Institute is of any value at all as an educational instrument, the admission of women to its privileges must tend to increase the chances open to them of obtaining lucrative employment.

I have no doubt that some one will reply that ladies do not want to come to our meetings. I am not at all sure that there may not even now be many who would be very glad of the privilege; but as we do not propose to force them to come, or to do anything beyond allowing them to come if they wish, I hardly see that the proposal is at all affected by any guess we may make on the subject. My own impression is that possibly, for a time, the privilege would be inoperative; then, when there happened to be a paper on in which ladies of advanced education take an interest, perhaps some members' wives or daughters might attend; and so it would go on till we came to look upon their attendance as a regular thing.

Someone else will, perhaps, object that we may get frivolous—society women invading our meetings, and disturbing the tranquillity of our discussions. It is, of course, very difficult to forecast what stupid antics fashion may decree, and we know that women have, at fashion's bidding, gone through very much more terrible ordeal than sitting out a discussion at one of our meetings; but I do not think we should be in much danger of such an infliction.

To the frivolous ladies whom we do not want, and to whom our discussions would bring no benefit, they would

be dryer than a fashionable sermon, and though they may not know much of many things, they do know when they are bored, and have the sense to keep away from boredom.

But I have a very much stronger argument for the admission of women of all grades to our meetings. I think it must be known to everyone that the extension of electrical enterprise will entail the bringing of electrical apparatus of all kinds within the home circle. Now, in my opinion, one of the greatest difficulties which promoters of these enterprises will have to encounter will be the want of knowledge of the users—principally women. A long experience in bringing forward new forms of apparatus has taught me that where you have any one on the ground who either understands the apparatus, or will take sufficient interest in it to master it, you will attain success with comparatively inferior materials; while you will fail utterly with the very best that can be produced if there is no one about who will take any interest in the matter. And of all offenders in this respect women are at present, in the great majority of cases, by far the worst.

Firstly, because they know nothing of electricity; and

Secondly, because they will not think.

If we are to succeed in superseding gas and other apparatus for domestic use, it will be an immense gain to us if we can teach women to think, and, above all things, to think about electricity; and I maintain that admission to our Institute will be the means of inducing both. Once the wonderful fascination most of us feel for the science gets hold of women, they will go right on and do half our work for us.—Yours, &c.,

SYDNEY F. WALKER.

[With regard to one part of Mr. Walker's letter, we may say that it is becoming customary to send out proofs of the paper to be read to gentlemen named by the author, or by the council, as desirous of taking part in the discussion. Mr. Walker's criticism had better be directed against authors who do not send in their MSS. sufficiently early to allow of its being put into type and corrected. We venture to surmise the stumbling block to the sending out of proofs as suggested is found at the feet of the author, and not elsewhere. Mr. Walker will, we are sure, understand that by making the above statement we have no desire to stop discussion, our object is to direct it towards the proper quarter. With regard to ladies at the meeting we are open to conviction either way.—ED. E. E.]

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

[CORRECTION. —The following corrections should be made in Mr. Kapp's paper in our issue of last week:—On p. 136, instead of $c = \sqrt{E}$ and $i = \sqrt{I}$, it should be

$$c = \frac{E}{\sqrt{2}} \quad \text{and} \quad i = \frac{I}{\sqrt{2}}.$$

Also, in the formula for E the exponent is 8, not 5—

$$E = 2\pi n F \times 10^{-8}.$$

THE DISTRIBUTION OF ELECTRICITY BY MEANS OF SECONDARY GENERATORS OR TRANSFORMERS.*

BY J. KENNETH D. MACKENZIE, MEMBER.

One of the difficulties which arises in all transmissions of electrical energy is the conveyance of a current suitable at one and the same time for any and every class of receiver. Each receiver requires, in order to work under proper conditions, a current suitable to itself, which current must have the proper proportions of potential and quantity. Now, as it is necessary, when the factor of distance is brought in, to increase the potential of the current in order to overcome the resistance due to that distance, it follows that receivers cannot be used which are not capable of supporting the particular current necessary to work them at increased distances. In the transmission of the current for glow lamps the distance is determined by the resistance of the lamps.

If it were a question what type of glow lamp is best, the reply would mainly be, that one whose resistance is the greatest—

* Paper read at the Society of Telegraph-Engineers and Electricians, February 9th, 1888.

other considerations, of course, such as efficiency, being equal. Should it be necessary to convey current for lighting purposes over a radius of several miles, the resistance then incurred would no longer be in proportion to the E.M.F. necessary to be employed. Likewise, in the transport of power over a given distance, if each motor corresponded to a certain construction, it would be necessary to modify and vary each one, according to its position from the main source. Lastly, if it were a question of transmitting electric energy to work at the same time are lamps, glow lamps and motors, the current suitable for one type of receiver would not be adapted for the others; in other words, according to the nature of the receiver employed, so must be also that of the current.

It was to overcome these most serious difficulties, which stood in the way of the practical development of electric lighting and transmission of power, that Messrs. Gaulard and Gibbs grasped the idea of interposing at the receiving point between the supply wire and the receivers a supplementary apparatus or generator, as a transformer of energy, which would deliver to the receiver

FIG. 1.

with which it was connected a current proper to such receiver. The secondary generators thus in a manner prepare and modify the current transmitted from the source, and give it the necessary proportions of potential and quantity which the particular receivers supplied by them require, in order to work at the highest point of efficiency.

This idea in itself was not new when M. Gaulard commenced his experiments, Jablockhoff, Fuller, Sawyer-Man, Sir Charles Bright, and many others having previously striven to bring the matter to a practical issue; but success did not crown their efforts, for the simple reason that the basis of all their experiments was the Ruhmkorff coil more or less modified, and it was only when M. Gaulard came to the conclusion that induction apparatus constructed upon the theory founded by Faraday, and exemplified by Ruhmkorff, was unsuited for the purpose, that a step was made in the right direction.

FIG. 2. -Faraday's Non-Polar Type.

The principles underlying transformers may be clearly seen by reference to Figs. 1, 2, 5, and 6, where what may be called the "Ruhmkorff and Faraday" type are shown, and the Gaulard type in Figs. 3 and 4.

In the figures illustrating this paper "primary" or inducing current wires are shown in black, and "secondary" or induced current wires by dotted lines.

In the Ruhmkorff type the secondary is either superimposed upon the primary, as in Fig. 1, or it is wound upon a core distinctly separate from, though contiguous to, the primary, and is alone acted upon by the magnetic changes set up in the core, as in Figs. 2, 5, and 6. It is for present purposes immaterial whether the core is polar or non-polar. In the Gaulard type the secondary is placed in an identical position in regard to the iron core with the primary, and is thus acted upon both by the core and the primary or inducing circuit, as in Figs. 3 and 4. This is one of the two principal features wherein the Gaulard-Gibbs transformer differs from all previous ones, the other principal feature being that the metallic mass of

When Messrs. Gaulard and Gibbs first exhibited their system at the Westminster Aquarium, in the beginning of 1883, only one transformer was there shown at work, and this one was consequently either in parallel or series with the dynamo. The advantages that would have resulted were a series system of connection possible being so apparent, M. Gaulard inclined more to this method of working, and used his best endeavours towards arriving at a successful result. He knew the impossibility of directly maintaining a constant potential in a secondary circuit whose resistance was being varied whilst the current in the primary was kept constant (an essential feature in series working), and therefore strove so to construct his apparatus that the action of the core upon the two conductors should vary with the alterations of resistance in the secondary. This he did by altering the position or exposing more or less of the core, and some attempts were made to effect this automatically.

As has been before said, the value of the secondary circuit varies directly with the square of the current in the primary, and directly with the number of turns; other considerations, such as the magnetic influence of the core and the number of current alternations, being constant.

The E.M.F. of a secondary circuit, however, is dependent upon another important factor, namely, the resistance to which it is opposed; and the following table of experiments made by M. Uzel, and published by Professor Galileo Ferraris in his report to the Jurors of the Turin International Exhibition, 1885, shows the increase of secondary E.M.F. with increase of resistance. It will be observed that the current in the secondary falls at the same time.

PRIMARY.		SECONDARY.		
A.	V.	A ¹ .	V ¹ .	R.
12.13	23.4	12.02	15.0	1.24
"	31.4	12.0	24.0	2.0
"	53.0	11.83	45.0	3.8
"	70.0	11.73	65.0	5.5
"	93.0	11.58	87.0	7.53
"	107.0	11.3	102.0	9.0
"	126.0	11.13	119.0	10.6
"	144.0	10.95	138.0	12.6

where A = amperes in primary, V = potential at poles of generator primary, A¹ = amperes in secondary, V¹ = potential at poles of secondary, R = resistance in ohms of the outer part of the secondary circuit.

It will thus be seen that the resistance in the secondary forms an all-important factor when designing apparatus for producing a required result; and a long series of experiments has established a certain ratio to be observed in order to obtain the effect sought for.

Experimentally it was found that with a certain current in the primary circuit of a given number of spirals or turns a certain electro-motive force was obtained in the secondary with a given resistance, and upon these data the construction and design of apparatus employed as series transformers were based.

The work done by the primary current when traversing a number of generators is proportional to the resistance offered by these generators, or, in other words, by the counter E.M.F. opposed to the primary current by the secondaries. This necessarily is proportional to the number in use, and also proportional to the individual resistance of each secondary.

It can therefore be seen that the total energy of the primary current varies directly with the amount of work done by the secondary circuits of the generators, thus enabling complete economy in working to be obtained.

The economy resulting from this system of working in series would be substantial were it also possible to ensure constancy of potential at the same time between the poles of the secondary with a varying resistance in that circuit. The difficulty is that the E.M.F. increases in the same ratio as with the resistance; and this, consequently, points to the fact that transformers, when connected in series, must supply lamps also in series, or, in other words, the external secondary circuit must diminish in resistance as the lamps are turned out, instead of increasing, as in the case when the lamps are in parallel. More than two years ago I made some experiments upon this subject with Mr. Bernstein, the results being perfectly satisfactory so far as regulation went. Another way out of the difficulty, if series transformers and lamps in parallel are to be used, is by the employment of subsidiary resistances, or "choking coils," as they are called, which take the place of the lamps when turned off. Fig. 9 shows this in a theoretical diagram.

With series transformers and series lamps, all danger from fire risk is reduced to a minimum. No main fusible cut-out at the transformer secondary poles need be used; for, as has been before said, if a short-circuit occurs, the potential immediately drops, so that the flow of current is consequently that due to the resistance of the secondary helix, including the short-circuit.

I have frequently run series transformers on short-circuit, and no heating has resulted, the potential at the terminals being imperceptible on a voltmeter, whilst the current indicated by an ammeter in the short-circuit was solely that due to the resistance of the ammeter and the secondary circuit of the transformer itself.

Another difficulty that lies in the way of working transformers in series is that experienced in maintaining a constant current on the line; and although many attempts have been made to do this automatically whilst employing alternating-current machines, no great success has as yet been attained.

Having briefly reviewed the system of working transformers in series, and shown the objections inherent to that method, I will now refer to the parallel system upon which all present installations are based—treating the subject in as practical a manner as possible.

At the outset one important feature, inseparable from all parallel systems of transmission of energy, may be mentioned, especially since it shows how, by the use of transformers, difficulties may easily be surmounted.

This is that the fall of potential along a line varies in proportion as the current is increased when changes are made in the load. The difference of potential between the source of supply and the extremity of the line is small when the current is small, but very considerable when a heavy current is used; and consequently, if the lamps near to the source be kept at a constant pressure, those far off will vary according to the intermediate load. In direct working this objection can only be met by employing a conductor of such size as will render the resistance of that conductor of no account, but then all considerations of economy will have to be abandoned.

This difficulty has been experienced in all large direct-supply works, since the fall of potential depends upon the ratio that the amount of loss on the line itself bears to the maximum amount of work carried by the line, this in many cases being quite 20 per cent. By employing a high potential, however, the current to represent a given amount of energy may be so reduced that this ratio may be made as low as 1 per cent. per mile, and consequently transformers in parallel are capable of maintaining practically the same potential in their secondary

Fig. 9.—Series Transformer Choking Coils.

circuits, irrespective of their position upon the line, or of the variation of the load at intermediate points. The following figures may make this matter clear.

Suppose a dynamo giving an output of 150,000 watts, equal to, say 1,500 amperes and 100 volts. If the conductor be proportioned so that one square inch of sectional area be used for every 1,000 amperes, the size of the conductor necessary will be 1.5 square inches. This conductor having a resistance of about .028 ohms per mile (neglecting heat resistance), the loss per mile on the line will be $1,500^2 \times .028$, or 63,000 watts—equal to about 42 per cent. of the total output of the dynamo per mile.

By the use of transformers, however, the same energy could be transmitted over the same distance with a very different percentage of loss. The output, being 150,000 watts, may be represented by a current of 50 amperes and 3,000 volts. The resistance of a cable required to carry this current, calculated on the same basis, would be about 864 ohms per mile, and the loss, therefore, would be $50^2 \times 864$, or 2,150 watts—equal to about 1.4 per cent. of the total load per mile.

These figures merely serve to show one of the enormous advantages that are reaped by the employment of transformers in the distribution of large amounts of electricity over great distances.

With regard, now, to the practical working out of a system of supply based upon parallel transformers, I will endeavour to show what has hitherto been done, the methods employed, and the results obtained.

The dynamo here claims our first attention, and, being the generating source of supply, forms, perhaps, the main feature in an electrical installation. In the first place, it must necessarily be of what is known as the alternating type. Up to very lately

this class of machine had in this country received but a small amount of attention; now, however, since the transformer system has become known and appreciated, several makers have gone into the subject, and many marked improvements have resulted. One of the chief of these is the employment of iron in the armature, and such good results have been obtained by making the mass of iron very considerable in both armature and field, that this plan is now regularly adopted. One of the most important points in this class of machine is self-regulation, more especially with regard to small variations in potential; the changes of load occurring on a supply system, which produce extensive alterations in the external resistance of the circuit, and consequently large variations in potential, being easily met in other ways, such as by the introduction, either automatically or by hand, of resistances into the exciting circuit, or by varying the speed of the machine itself. As much as 2 volts per foot of wire may be obtained from the armature of a dynamo without any very considerable speed; and it is of importance to get this amount, if not more, when we remember that the magnetising effect of the current in the armature coils, as well as the amount of self-induction, is proportional to the number of turns in the coils.

Now, since both are objectionable when amounting to much, high E.M.F. and steadiness of potential may be obtained by greatly increasing the mass of iron, so that half saturation is never exceeded. Some very large alternating-current dynamos are now in use in this country, probably the largest being those by Ferranti, employed at the Grosvenor Gallery Central Station. Others, by the same maker also, are now in hand for the new supply works of the London Electric Supply Corporation, Limited, at Deptford, whose dimensions appear rather formidable. Their armature are to be, I understand, about 42ft. in diameter, and will be driven direct from quadruple expansion compound surface-condensing engines of a marine type, indicating 5,000 h.p. each.

A type of alternating-current dynamo is shown in Figs. 10 and 11, which, though founded on a system previously known

FIG. 10.—Kingdon's Dynamo.

and patented, has lately been altered so as to render it workable and efficient by Mr. Kingdon, who, early in 1886, submitted to me his ideas upon the subject. Those who had previously worked in the same direction had failed to make a serviceable machine from having overlooked the importance of laminating all the iron acted upon electrically, as well as other minor details requisite to make the idea practicable.

A series of bobbins, whose cores form parts of one whole continuous iron structure made of laminated soft iron plates, are divided into two divisions: one of these is rendered magnetic by separate excitation, and is shown in the figure by black lines; the other, as shown by dotted lines, is acted upon inductively by the revolving laminated inductors, which may form part of the fly-wheel of an engine. It will be seen that if the black bobbins be coupled up and excited they will each have an alternate polarity, and that if an iron armature or inductor be placed across the pole of one of these bobbins and the pole of the next non-excited bobbin, a current will be set up in the wire forming this second bobbin, which current will tend to make its core of an opposite polarity to the one next it, and which is joined with it by the inductor. As the revolving inductor alternately connects the induced bobbin with its neighbours, each of which has an opposite polarity, it follows necessarily that the current that will flow in the induced bobbin will be alternating.

I would draw your attention here to one striking feature in the machine, viz., that the same mass of iron serves both for the field magnets and the secondary coils, there all being, so to speak, no sections or teeth of the iron mass. A series of alternate bobbins, excited and not excited, if magnetically connected in the manner by revolving inductors, will yield a current from these bobbins not separately excited, which current will depend in its value upon the strength of the magnetic field due to the excited bobbins, the size of the induced bobbins, the quantity

and dimension of the wire thereon, and the speed at which the inductors revolve.

Experiments made with a dynamo of this nature have so far given very good results, some of the main advantages that may be claimed for such a type of generator being that there is no revolving or moving wire, no collectors and consequently loose contacts; that the machine may be divided into separate circuits, which, by means of a switch-board, can be easily varied; and, lastly, that very great simplicity of construction, and consequent low cost, is obtained. The fly-wheel of the engine may carry the inductors, and as this can easily be made of very great size, slow running machinery may be employed, with its consequent advantages.

In designing supply works for electric lighting on a large scale, I am of opinion that the employment of a few very large dynamos, instead of a larger number of smaller ones, is a mistake, and that, generally speaking, the output from each dynamo should not exceed 10 per cent. of the total capacity of that particular station. In all running machinery, be as careful as one may, accidents will happen; hot bearings will, when least expected, occur; and with a heavy load on an engine running under such conditions serious damage may be caused, whilst, if a stoppage be made, a very heavy proportion of the total output will be affected. It is true that with a larger number of small engines the initial cost is greater, the depreciation greater, maintenance and attendance more costly; but, nevertheless, I am inclined to think that these disadvantages are more than counterbalanced by the greater security gained in subdividing the producing plant to a larger extent, especially when it is remembered how important it is in works of this nature that no breakdown in the supply should occur.

It may be well to remark here that it has been found quite practicable to couple alternating-current machines in parallel, so as to throw them in and out of circuit whilst current is on the line. Messrs. Zipernowski effected this some while ago,

FIG. 11.—Kingdon's Dynamo.

and I find that the Westinghouse Electric Company also work their machines thus. Practically speaking, all that is necessary is to synchronise the dynamos, and whilst their alternations are thus synchronous they can be coupled together or disconnected at will.

I cannot speak from much experience myself on this subject, having only experimented with some of Messrs. Siemens' machines. I found, however, that whilst it was possible to synchronise them and couple them in parallel, yet the slightest thing would throw them out of gear, if I may so speak, and destroy the balance. Even a small piece of waste falling on the belt was sufficient to do this.

With dynamos, however, having a large mass of iron in the armature, I believe it to be much more easy to couple them together, and this may be the reason why others have had more success than myself. The subject is an interesting one, and of great importance, I think, in large central stations employing alternating currents and transformers.

Until some practical means of electric storage, suitable for installations of this nature, be devised, the whole question of electrical distribution cannot be said to be completely solved. In gasworks plant can be laid down which will continually produce gas, which can be stored and drawn upon during the few hours in which the demand is greatest; but with electric lighting, if carried out on a large scale upon this system, it is necessary to furnish plant capable of meeting the maximum demand, although such demand may only exist during one hour in the twenty-four. This necessitates the machinery standing idle during a part of the day, and consequently loss through unprofitable employment of capital; hence it is most essential that due care and forethought be exercised in arranging the number and sizes of engines and dynamos in any specific installation.

(To be continued.)

LEGAL INTELLIGENCE.

CRAMPTON v. SWETE AND MAIN.

On the 11th inst judgment was given in this case by Mr. Justice Kekewich. Briefly the plaintiff, Mr. T. P. C. Crampton, was a working electrical engineer, his business consisting almost entirely of the manufacture of electric bells according to an invention for which he obtained provisional protection on the 2nd of February, 1886. In the present action he seeks to restrain the publication by the defendants (who are electrical engineers of 11, Queen Victoria-street, E.C.) of the following circular, which he alleges to be false and malicious and in effect a trade libel:—"Manson House-chambers, 11, Queen Victoria-street, London, E.C., October 7, 1886. Messrs. Swete and Main beg to inform you that they are unable to supply under any circumstances the Crampton patent bell, as this bell has proved to be an infringement of the Jensen bell. Such bells as have been sold to you by Messrs. Swete and Main are exempt from an action for infringement by Mr. Jensen, the royalty money having been paid thereon by Messrs. Swete and Main." The plaintiff's contention was that the circulars imputed that the plaintiff's bells had been proved in a court of justice to infringe the Jensen bell. As a matter of fact, there was no action pending against the plaintiff at the time when the circular was issued. An action had subsequently been commenced against him for infringement by the Patents Investments Company, to whom the Jensen bell patent has been assigned, but this action is still pending and is being defended by the plaintiff.

Mr. C. E. E. Jenkins and Mr. C. H. Tylor were for the plaintiff; and Mr. Roger W. Wallace and Mr. Williams for the defendants.

Mr. Justice Kekewich, in delivering judgment, said the case of the plaintiff was that Swete and Main had by issuing the circulars to their customers (some of whom had been introduced by the plaintiff) practically destroyed his business. The circular was wrong until it could be proved to be innocent by being shown to have been issued with reasonable and probable cause. The defendants had referred to Section 32 of the Patent Designs and Trade Marks Act, 1883, but that had as much to do with this case as any other section of any other Act. Something must be necessary to show that the words, "have been proved," were properly used. "Proved" meant established. At this time the defendants did not know that any litigation was pending. The statement, though the defendants did not mean to do wrong, was untrue; and the plaintiff had thereby suffered damage, which his lordship assessed at £20. The defendants counter-claimed for damages for misrepresentation, but this claim failed. They also claimed for the price of a lamp. The plaintiff must return the lamp on payment of 11s. 6d., but the defendants must pay the costs.

COMPANIES' MEETINGS.

TAUNTON ELECTRIC LIGHTING COMPANY (LIMITED).

The first annual general meeting of the shareholders of the Taunton Electric Lighting Company (Limited), was held last week at the Castle Hotel, under the presidency of Mr. W. H. Fowler, chairman of the board of directors.

The Chairman read the report, which was as follows:—"Your directors have pleasure in presenting herewith the first annual report of the Company. The number of shares allotted is 873, on which the sum of £4,365 has been received, including the amount allotted on account of the purchase of the business. The number of private customers is now 20, besides the town lighting, and the number of arc lamps let at a rental is 65, besides the incandescent lamps in use, numbering 200. The accounts for the year show a profit of £315 15s. 5d. Your directors recommend that a dividend of 5 per cent. be paid free of income tax. This will take £191 19s. 6d., leaving a balance of £123 15s. 11d. to be carried on for a reserve and depreciation account. In addition to the Taunton business the Company has carried out temporary installations in Bath, Weston-super-Mare and Exeter. Deputations from various places have visited Taunton during the past year for the purpose of inspecting the Company's works, machinery, and the lighting arrangements of the town, the general testimony being that it is one of the most successful installations yet carried out in the United Kingdom. The machinery has been maintained in excellent working order, those portions of it which are continuously wearing out being made good, and charged to income account. As the demand for the

light increases, it is expedient to lay down more plant and machinery, and to enable the directors to do this they hope that the public generally will take up more shares to increase the capital available for this purpose. Two of the directors retire by rotation, and are eligible for re-election. The names of the retiring directors to be decided by ballot will be announced at the annual meeting. The auditor, Mr. Albert Goodman, retires, but is eligible for re-election, and offers himself accordingly."

The Chairman then moved: "That the report of the directors and statement of account be received and adopted, and a dividend of 5 per cent. per annum, free of income tax, be declared payable on and after the 13th instant." He remarked that it was his pleasing duty to have to propose the adoption of the report at the end of the first year of the existence of the Taunton Electric Lighting Company. They must all consider it a very satisfactory matter that they had been able, in spite of the many difficulties that stood in their way, to show that electric lighting could be made pay, and to declare a dividend of 5 per cent., which they had fairly earned. It was very necessary for the well being of the Company that the capital should be considerably increased, and they had reason to hope that in the immediate future a sum of at least £1,500 would be forthcoming, which would enable them to extend their sphere of usefulness to a large extent. He hoped that in the future they would also be able to pay a better dividend than that which they were able to announce that night. They had to pay a large sum for the exclusive right to use the Thomson-Houston system in Taunton, which, of course, would always remain, but the larger the amount of work they did the better it would be, as far as their dividends were concerned. A ballot had been taken to decide the order in which the directors should retire, with the result that Mr. Sanson and Mr. Lewis would retire in 1888; Mr. Hale and Mr. Withycombe in 1889; Mr. Potter and himself in 1890.

Mr. W. Potter had very great pleasure in seconding the resolution. He was sure it was a matter of congratulation to the directors to see the shareholders so well represented that night. At some annual meetings which he attended the shareholders were conspicuous by their absence, and the whole business of reading and adopting the report and passing resolutions—including votes of thanks to the directors—devolved upon the directors themselves. On such occasions the directors flattered themselves that it was a proof that they enjoyed the confidence of the shareholders, but he knew that when the shareholders attended the annual meeting in large numbers it was more satisfactory to the directors, because it showed that they felt an interest in the Company's affairs, and it gave an opportunity for discussion, during which valuable suggestions were often made which might prove of the greatest usefulness. They would all agree with the chairman that the report which had been read was a very gratifying one, not merely because it declared a dividend of 5 per cent. on their investment, because that was seemed to them from the very first by their managing director as the vendor to the Company, but because the Company in the first year of its existence had made such profit as to justify the directors in declaring that dividend out of the actual profits made during the year. It would be gratifying not only to the shareholders, but to the general public, inasmuch as it would go a long way to secure that public confidence and support which were so essential to the commercial success of an undertaking such as that. They had met with people who professed very much to admire the electric light and wished it every success, but who were reluctant to take shares in the Company until they saw that it was going to be a financial success. The fact was, public confidence in electric lighting as a commercial success sustained a shock by the collapse of the companies formed some years ago. Electric lighting seemed to him to have been prematurely thrust upon the public. It had many imperfections, and was produced at very great cost, and the consequence was that it proved disastrous to those who invested in it, but within the past few years very great improvement had been made in electric lighting, and its production now was far less costly than it was then. It seemed to him that it had at the present time all the elements of commercial success, and it was, as they knew, rapidly rising in public estimation and confidence, and there was every reason to believe that the failures of the past would prove the precursors of its future success. He need not tell them that the electric light had brought the town into notice in a manner nothing else had ever done. It had been a most effective advertisement to the town, and it had undoubtedly brought increased trade into it, in which all classes of the community must participate. There was not the slightest doubt that by means of the electric light the town had been so advertised that many who before were altogether ignorant of the existence of such a place as Taunton, or if they did know anything of it, regarded it as a writer in the *Daily Telegraph* did a few years ago, as "a village in the West of England," now, by means of the electric light, knew it as an enterprising town, beautifully situated and possessing many residential attractions. He thought they might confidently expect that still greater benefits would accrue to the town as a result of their enterprise in that respect. Such being the case, and he was convinced that it was so, it seemed to him that it was the duty of the trading portion of the town especially to interest themselves more in this matter than they had done hitherto, and to do everything they could to make the electric light a success, and also to share some portion of the responsibility. That, it must be confessed, had not been done to the extent it was hoped and expected it would be. The responsibility and burden had been left in the hands of a few who had had to push the thing not only against indifference but determined opposition. That the introduction of the electric light into Taunton would be met with opposition was well known. The directors knew perfectly well they would have opposition to contend with, and they were prepared for it. They had the light of history to teach them in that matter—that opposition attended the inauguration of every new movement. However beneficial it might be to mankind it was always assailed with opposition, springing from two sources—the first from indifference, and the second from mistrust of anything that

had not proved itself to be an established success. People moved in the old ways and thought on the old lines, and regarded with aversion anything likely to contradict their preconceived notions or falsify their theories. In addition to this there was always opposition arising from vested interests. It was an omnipresent obstacle to all improvements. People objected to companies because they would touch some one in the sensitive part of his nature, viz., his pocket. The opposition they had to contend with the shareholders knew had been very great, and possibly it might be traced to one or other of these reasons. They knew that some measures which were now admitted to be of incalculable benefit to the human race were at first met with determined opposition. He thought this explained the damaging statements that had been made with reference to the electric light. It was just the same when railroads and machinery in agriculture and manufacturing industries were first introduced; the inventors and promoters were assailed with very harsh language and treated in a very unkind and ungenerous manner, simply because it encroached on some one's pocket, or in some way or other interfered with the employment of the few, although by the starting of those new industries employment was given to the many, whilst the profits of the few were curtailed the whole nation was enriched. The very same opposition that was manifested towards the introduction of railroads and steam power was now persistently shown against this new illuminant. The fact was there were many who were afraid that if the electric light proved a success the result would be a lower rate of dividend in the gas shares, but why this should be so he did not know. If it were true, and he had no doubt it was, because he had been told it on the testimony of those in whose veracity he had the fullest confidence, that street lighting did not pay the Gas Company, and that the directors of the Gas Company were glad they had the electric light in the streets, then they might reasonably expect to find in the directors and shareholders of the Gas Company their warmest friends and advocates of the new light. But it was not so; they found that some of the most damaging statements that were likely to affect the credit of the Electric Lighting Company and prejudice the minds of the community against the light had originated mainly from those who had been holders of gas shares. Fortunately some of the statements that had been made were so palpably absurd that they had not required any refutation from the Company—they had carried their own refutation in their absurdities. For instance, they were told that the electric light, instead of being what it professed to be—viz., 1,200 candle power, was only 200. He admitted he had too high an opinion of the gentleman who made that statement to suppose that he was in error; he believed it. He would not insult his intelligence by supposing that he believed the lamps only gave 200 candle power instead of 1,200, but in such a statement they had a striking instance of man voluntarily degrading his intelligence for the sake of his pocket. Other statements were that the installation was very costly, that it would not last more than three years, and that the atmospheric influences were such that at the end of three years the present system would be useless. That was a very serious matter, and certainly affected them so vitally that he had not merely ascertained the opinion of their own electrician upon it, but he had mentioned it to gentlemen of reputation who had no connection whatever with that Company. They both assured him that such a statement was an absolute fallacy, and that it was void of any foundation in fact. They were told not merely by their opponents, but by those who were favourable to the light, that it was not so good as it was. They heard the contrary from both their electrician and those who knew said that a possible explanation was to be found in the fact that they had now grown accustomed to the light, and they knew the old stage that "familiarity breeds contempt." He mentioned this to the electrician whom he had referred to, and he said, "Yes, it is always the way. I will give you an instance. A short time ago I fitted up a large factory at Nottingham, a factory employing some 1,500 hands. People were charmed with the light, it went on satisfactorily for some months, and then they said it was not so good as it was formerly, and they made a great many complaints. Representatives of the factory said, 'We will turn on the gas again.' Thereupon, and the result was that the whole mass of people rose and saying they would not work by such light, and unless the electric light restored they would go out on strike." The electrician in question assured him that in his experience he had found it over and over again that after a time people became accustomed to the light and said it was not so good. The present installation might not be perfect; it would not claim perfection for it. It might be, in comparison to what that science should evolve in the future, as imperfect as the contrivances of Stephenson were to the powerful engines which they saw every day at the railway station—the Zulu and the Flying Dutchman—it might be that the present system of lighting was as crude as compared in comparison with that which might yet be evolved as the "steaming Jenny" of Arkwright was to the steam power of mechanism which might be seen any day in our modern contrivances, and which, from the splendid manner in which they performed their work, seemed to be almost instinct with divine intelligence. The directors, in the future, would not pursue a policy of inactivity. Any improvement that could be effected by the more light could be secured, or the position of the Company would be adapted by them, in the hope that if they were not, like American companies, able to declare a dividend of from 8 to 10 per cent., they would year by year be able to declare a dividend of 5 per cent., and so merit their confidence and support.

A resolution was carried.
Mr. Newman and Mr. A. Lewis were re-elected directors. Capt. Newman and Mr. C. E. Lewis were also elected on the directorate, making the total number of the directors to nine. Mr. Massingham was elected managing director.

In response to his resolution, Mr. J. H. Bale stated that the success of the Company had been largely due to Mr. Massingham's able management.

Mr. Massingham, in returning thanks, said it was a great pleasure to occupy the post, because he took a keen interest in the lights of the future. He was pleased that the prophecies which had been made about them at various times had proved to be false. They were expected to come financially and technically to disaster, but they had proved a success, showing that it was not always wise to prophesy unless they knew.

The Chairman said that Mr. Wharton, a member of the firm of Messrs. Lang, Wharton, and Down, was present, and no doubt the meeting would like to hear him upon the subject.

Mr. Wharton congratulated the shareholders on the very satisfactory result which had been arrived at on the year's working. The name of Taunton would be very much advertised from that night forward. It would go throughout the length and breadth of the country that the Taunton Electric Lighting Company had declared a dividend of 5 per cent., which was unique in the annals of electric lighting. Taunton was the pioneer installation in this country, a sound commercial installation on the American system. Central stations had been started in various other towns in the country, but they had not been a success themselves. In Brighton, Eastbourne and Hastings central stations were started some years ago, and very large sums of money had been spent, running into hundreds of thousands of pounds, and the result commercially was almost nil. He was glad to say that Taunton, which was the first town in the country to adopt the Thomson-Houston system, was the first town to possess an electric lighting company of their own which was financially and technically a success. The following appeared in the electrical papers recently:—"The second meeting of the Electric Lighting Committee of the Bath Town Council took place on Thursday, at the Guildhall. The chairman said he had much pleasure in laying before the committee the information asked for at the last meeting. With a view to obtaining it from the most reliable and independent sources, he had written to the scientific and technical papers devoted to electrical engineering, asking in what towns in the United Kingdom the electric light had been adopted, and in what places it had proved successful, or been abandoned. After a long discussion it was pointed out that all agreed that the most successful installation was the one at Taunton, and the town clerk was requested to put himself in communication with the town clerk of that town, and ascertain particulars respecting the system in use there, and report the result of his enquiries at the next meeting." Speaking of the success of the firm he said that the total number of Thomson-Houston arc lamps running in the United States was 50,000, and there were over 300 local companies like theirs at Taunton, all earning good dividends. The total number of incandescent lamps erected last year was over 200,000. Negotiations were nearly completed for nearly half a dozen such plants as that at Taunton, and the Midland Railway Company had decided to use the Thomson-Houston system for lighting St. Pancras Station. The Company had investigated all the systems, but hitherto they had maintained electric lighting was not complete enough for their purpose. If this experiment succeeded the light would be used on other parts of their system, and the London and North-Western Railway Company might probably follow suit.

The proceedings then terminated.

SUBMARINE TELEGRAPH COMPANY.

The half yearly general meeting of the Submarine Telegraph Company was held on Tuesday at the offices, Throgmorton Avenue.

The Hon. H. B. Brand presided, and, having apologised for the absence of Sir J. Goldsmid, M.P. (the chairman of the Company), who is abroad, stated that the directors had asked him to preside because he had been associated with the chairman in negotiations with the English Government on matters seriously affecting the interests of the Company. The accounts were very simple, the only item calling for remark, perhaps, being the considerable increase in salaries and wages. The moiety of that increase was explained by the fact that there had been 27 pay days in the half year while the takings had been for only 26 weeks. The balance of the increase was explained by the necessary growth of the salaries. Their business had been subject to very little fluctuation. The accounts enabled the directors to recommend a dividend at the rate of 15½ per cent. per annum, to allocate the usual amount to the reserve fund, and to carry forward a small increase. He was quite sure, however, that their minds were occupied with the matters which affected the existence of the Company, and therefore he would inform them of the position with reference to the renewal of the Company's concessions. At two or three of their last meetings the chairman had deprecated any discussion on that question, and it was obvious that no advantage could be gained by making public the course of their negotiations with the French Government. At the same time, the chairman, in guarded language, expressed his belief that they would be successful in obtaining a renewal of their concession from the French Government. The chairman was perfectly justified in that. They had actually received an intimation from the French Government, of which M. Rouvier was Premier, that the renewal of the concession would be granted by that Government for a period of years on terms agreed on between them and the Company, when the English Government interposed and requested the French Minister to disavow the agreement until he had had the opportunity of considering the alternative policy of the English Government to place the administration and working of the cables between England and Belgium and England and France in the hands of the Governments of the respective countries. For lingering about the success of the Company so far with the French Government, their chairman and Sir James Carmichael were to be thanked, and they were ably seconded by Count Dillon in Paris. He considered, and the directors considered, that the action of the English Government was a breach of faith with the Company. They had passed that point on the Government but Governments had no conscience. If it were said that what proposed

was for the public advantage, something might be said for the policy; but it was not, he maintained, for the public advantage. The public could obtain every advantage from the Company that the Post Office could give them. It was a mistake to suppose that the tariffs had been settled by the Company; they had been settled with the Government by agreement with the Company. The action of the Government was not likely to stimulate and encourage private enterprise. Their former chairman, the late Sir James Carnichael, and the other concessionaires were the pioneers of submarine telegraphy in this country. He had said that what was proposed was a gross breach of faith by the English Government, and he would tell them why. In 1868, when the Government purchased the inland telegraphs, the Company entered into a working agreement with the Government for the transmission of messages along the inland lines. Ten years later the Government, being desirous of getting better terms, entered into a fresh agreement with the Company, by which, on the one hand, the Government invited the Company to obtain a renewal of the concessions from the French and Belgian Governments, and, on the other hand, the Company undertook, so soon as they obtained such renewal, to give terms to the Post Office more advantageous than those which had been fixed by the agreement of 1868. The Government now alleged that that agreement had become null and void by the failure of the directors to obtain an earlier renewal of its concession from the French Government and by lapse of time. Their failure to obtain an earlier renewal of the concession from the French Government had not been owing to any fault on the part of the Board, but to the fact that they were always met by the refusal of that Government to enter on a consideration of the matter until the expiry of the whole concession had arrived. But apart from that, the lapse of time and the failure of the directors to obtain an earlier renewal of the concession formed no justification for the action of the English Government. They entered into an agreement with the Company in 1878, and invited the Company to obtain a renewal of the concession from the French Government; and from that time until last November they had never intimated to the Company that not only in their opinion was the agreement cancelled but that they intended to oppose actively the renewal of their concessions. They had urged that the Government ought to have regard to the circumstances he had mentioned in fixing the price to be paid for the Company's undertaking. There remained, however, the decision of the French Government, and also the question of the decision of the English Parliament. For his part he hoped that some effort would be made to point out the danger of the extension of Government business. If these undertakings were brought up, he was not very sanguine that the terms would be such as the shareholders and the directors would consider highly satisfactory, but he was happy to say that they had got the Government to assent to two principles for which the Board had contended, and to which they attached the utmost importance, but respecting which he would say no more at present. He concluded by moving the adoption of the report.

The Hon. Ashley Ponsonby seconded the motion.

Mr. King said he still hoped they would have justice done to them by the British Government, but if not they must go to the Court of Appeal and to Parliament.

Mr. Soden spoke of the danger which, in his opinion, the taxpayers incurred by the Government embarking in risks and responsibilities with foreign Governments in order to acquire the submarine telegraphs. The Government had arbitrarily intimated their intention to revoke the license which the Company had held for 30 years for the use of the foreshore. Every other submarine cable company carrying on business between this country and any other part of the world might at any time receive a similar intimation from the Government, and he, therefore, urged the advisability of the various companies combining. If the Government had paid too dearly for the inland telegraphs, that was no reason why they should now try and commit an act of injustice.

The Chairman put the motion, which was carried, and the dividend recommended was afterwards approved.

COMPANIES' REPORTS.

THE SWAN UNITED ELECTRIC LIGHT COMPANY (LIMITED).

Fifth annual report of the directors, to be presented at the ordinary general meeting of the Company, to be held at the Cannon-street Hotel, London, on Tuesday, 28th February 1888, at 12 noon.

The accounts which are herewith presented to the shareholders are for the year ending 30th September, 1887. The business has grown, and has resulted, after paying all current charges and making fair allowance for depreciation of plant and machinery, in leaving a sum of £7,554 11s., which the directors recommend shall be applied to the writing off of £5,834 3s. 1d., the amount which stands against profit and loss, carrying forward £1,720 7s. 11d. The directors have resumed negotiations with the Compagnie Continentale Edison, with a view of arriving at an equitable settlement in the countries in which they hold patents in connection with electric lamps. Should these negotiations result in any plan which the directors regard as beneficial for the Company, they will call a special meeting of the shareholders. In their last report the directors stated that they were led to believe that a decision in the patent suit would shortly be given by the judges in the Court in Berlin. The case has dragged on during the year, but judgment has not yet been delivered. Competition is very keen on the Continent, but the Swan lamp is undoubtedly the best in the market. The sales have increased during the year considerably, and the demand for lamps during the winter months has been largely in excess of previous years.

THE BRIGHTON ELECTRIC LIGHT COMPANY (LIMITED).

Second annual report of the Brighton Electric Light Company's operations for the fifteen months ended 31st December 1887.

The directors have pleasure in submitting to the shareholders the report of the operations of the company from the 1st October, 1886, to the 31st December, 1887. The capital account has, during this period, been augmented by the sum of £2,100 which has enabled the company to increase their engine power and dynamo capacity, and to largely extend the circuits. The profit and loss account after writing off the special legal expenses of the year, and an ample sum for depreciation of plant shows a balance of profit for the fifteen months of £721 16s. 6d. which, with the small balance brought forward from last year's accounts makes the sum to the credit of profit and loss account £729 0s. 11d., and the directors recommend the following appropriation of it:

Dividend of 5 per cent. per annum, on the share capital	£568 16 10
Liquidation of the balance of the preliminary expenses account	89 16 2
Carried forward to next year's profit and loss account	70 7 11

£729 0 11

There has been a steady increase in the Company's business during the period under review. The mains belonging to the Company now extend a distance of 15 miles, reaching westward as far as King's Gardens Hotel, eastward as far as Eastern-terrace, Kemp Town; and northward as far as Haverover-essent, Lewes-road. One reason of this increase of business, and of the probability of its further development, is the extension of the Company's mains into Hove. As that district consists almost entirely of the residences of the wealthy, a practically unlimited field is thereby opened to the company. The directors have considered it desirable, in order to be in a position to cope with their increasing business, to still further increase the dynamo power, to extend the company's circuits, and to gradually place "converters" in all the premises lighted, by means of which it will be possible to turn lights on and off one by one when required. The cost of the proposed extensions will be about £2,000, and the directors propose to cover this sum by a further issue of share capital. Preference will be given to applications received from residents in Brighton and Hove, especially from those who are customers of the Company, as the directors are anxious to widen the local interest in the concern. The contemplated addition to the plant will bring up the total dynamo capacity to over 2,500 sixteen candle-power incandescent lamps, the present engine power being capable of driving dynamos for 3,500 lamps, so that the capacity of the plant can be enlarged to this extent by the addition of new dynamos at any time when required. The nature of the improvement in the company's business may be seen by the following statements.

May	971	1,031	7
June	703	1,016	45
July	701	1,093	56
August	1,462	1,845	26
September	1,846	2,909	63
October	2,633	3,368	50
November	2,984	5,427	81
December	3,175	6,372	101
Totals	26,257	41,309	56%

It will be noticed that, whereas the total business shows the satisfactory increase of 41,309 units as compared with 26,257 in the former period of fifteen months, the most recent improvement is still more marked, the units consumed in December, 1887, being 6,372, as against 3,175 in December 1886 and the consumption in the quarter ended December 31st, 1887 15,767 units, as compared with 8,796 units in the corresponding quarter of 1886. In view of these figures, the directors feel confident that, with the proposed additional machinery at their command, they will be able, during the current year, to considerably augment their gross receipts, and as the expenses will not grow in anything like the same proportion, a substantial improvement in the profits will, in their opinion, result.

The following is a list of the present installations of the Company, London, Brighton, and South Coast Railway Station, the Grand, Bedford, Clarence, Quadrant and Gloucester Hotels, The Orleans and Union Clubs, the Oxford Music Hall, the Chapel Royal, the Sussex Daily News Office, the Swiss Mountain Railway, the private houses of Sir Albert Sassoon, Ranien Sassoon Esq., Arthur Sassoon Esq., Panmure Gordon Esq., Frederick Shoolbred Esq., James Willing Esq., G. Atter, Esq., Sen., G. F. Atter, Esq., Jun., P. W. Jowers, Esq., M.D., G. R. Miller, Esq., Charles Galt Esq., Charles Lamb, Esq., Edward Scott, Esq., Colonel Tamplin, Frederick

Deane, Esq., and W. J. Smith, Esq., the offices of James Walling Esq., G. Attree, Esq., Messrs. Tappin and Son, Messrs. J. L. Denman and Co.; the boarding houses of Mr. A. F. Lamotte, the Delley, and Dr. J. L. Gore, Connaught House, Mr. Bichel, Polydore Mansion; and Mr. Worth, Haslemere House, and the following shops: Messrs. Wells and Co., Messrs. Louis Wolff and Co., Messrs. Hemmelsberg and Pool, Messrs. Williams and Co., Messrs. Pope and Son, Messrs. Cheeseman and Co., the Waterproof Stores, Photographic Company (Limited), Messrs. Allen and Thompson, Messrs. Lewis and Son, the Drug Stores, Mr. Lechard, Mr. Soper, Mr. Ullman, Mr. Lawson, Mr. Green, Mr. Lawrence, Mr. Kemp, Mr. Baker, Mr. Stevens, and Mr. Munden.

Mr. Arthur Wright, who, while in the employ of Messrs. Hammond and Co., started the works at Brighton in conjunction with Mr. Robert Hammond, and who has brought them to their present state of efficiency, has continued to act as managing director; and the thanks of the shareholders are due to him for the highly satisfactory manner in which he has conducted the business of the Company during the period under review. He reports that the engines and dynamos have continued to give satisfaction and are at the present time in thoroughly good working order. There has not been one single breakdown of the machinery during the fifteen months. The whole installation is in a much higher state of efficiency than it was at the date of the last report.

PROVISIONAL PATENTS, 1888.

FEBRUARY 3.

1649. The sectional vulcanised fibre electrical incandescent lamp cap and crown. William Davis and Thomas James Turner, Nin Court, Throgmorton-street, London, E.C.

FEBRUARY 4.

1681. Improvements in electrical appliances and apparatus connected therewith. Walter Thomas Gooden and Llewelyn Birchall Atkinson, 25, Andalus-road, Clapham, S.W.

FEBRUARY 6.

1733. Improvements in the method of and apparatus for depolarising the negative elements of galvanic batteries. William Joseph Starkey Barber Starkey, 70, Market street, Manchester.

FEBRUARY 7.

1786. Improvements in telephonic transmitters. Thomas Laurie, 115, St. Vincent street, Glasgow.

1818. Tanning by electricity, in a tanning pit or trough, the combination of motionless hides, skins, &c., with a circulating tanning liquor traversed by an electric stream. George Walter Rhodes, Friern Park, North Finchley, Middlesex.

1836. Improvements in the construction of apparatus for communicating currents of electricity to persons on the introduction of specified coins or checks. James Tarbatten Armstrong and Auguste Semmler, 8, Quality-court, London, W.C.

1843. Improvements in rheostats and rheotomes. John Clayton Newham, 169, Fleet street, London. (La Société Anonyme pour la Transmission de la Force par l'Electricité, France.)

FEBRUARY 8.

1862. Improvements in the manufacture of carbons for electric purposes. Augustus Tack, 15, Bennett park, Blackheath, London, S.W.

1875. Improvements in dynamo-electric machines and in electro-motors. George Hookham, 7 and 8, New Bartholomew street, Birmingham, and Robert Holden Housman, Perry Hall, Birmingham, Worcestershire.

1876. Improvements in the armatures of dynamo-electric machines and of electro-motors. George Hookham, 7 and 8, New Bartholomew street, Birmingham.

1891. A flexible battery cell and method of arranging the elements therefor. Mark Bailey and John Warner, 21, Finsbury-pavement.

1919. An improvement in arc electric lamps. Arthur James Hoares, 28, Southampton buildings, Chancery-lane, London, W.C.

1926. A mechanical chair or seat for the delivery of a current of electricity upon the insertion of a coin. Henry Charles Lush and Arthur Ford Lloyd, 28, Clipstone-street, London, W.

FEBRUARY 9.

1932. Improved forms of electrical contacts for switches and similar fittings. F. H. Royce, Blake-street, Hulme, Manchester.

1994. Improvements in electrical switches suitable for incandescent lamps. Frederick Thomas Schmidt, Sunbridge chambers, Bradford, Yorkshire.

1998. An improved secondary battery or accumulator for the storage of electricity. Walter Tilly, 11, Lewes-road, Brighton.

1987. A new or improved electro-motor. Thomas Parker, of the firm of Elwell-Parker (Limited), 70, Market-street, Manchester.

1988. The manufacture of nickel electro-types. Thomas Leman Matthews Hare and Louis Benureau, 31, Essex-street, Strand, London.

COMPLETE SPECIFICATIONS ACCEPTED.

MARCH 2, 1887.

3225. Improvements in and relating to the generation and distribution of electric energy and machines or appliances therefor. Robert Dick and Rankin Kennedy, 96, Buchanan-street, Glasgow.

MARCH 17, 1887.

4032. Improved holder for brushes of electro-motors and dynamo-machines. Moritz Immisch 53, Chancery lane, London.

MARCH 22, 1887.

4322. Improvements in dynamo-electric machines. John Hopkinson and Edward Hopkinson, 47, Lincoln's Inn fields, London, W.C.

MARCH 25, 1887.

4472. Improvements in electro-deposition of cobalt. Silvanus Phillips Thompson, 423, High Holborn, Middlesex.

APRIL 4, 1887.

4978. An improved holder and switch for electric lamps. Frederick Thomas Schmidt, Sunbridge Chambers, Bradford, Yorkshire.

4980. Improvements in apparatus for making and breaking electrical circuits in connection with call or alarm boxes. Frederick Thomas Schmidt, Sunbridge Chambers, Bradford, Yorkshire.

5009. New and improved methods of charging and re-charging, cleansing, changing and varying the chemicals and liquids used in secondary batteries or accumulators. James Tarbatten Armstrong, 8, Quality-court, London, W.C.

APRIL 5, 1887.

5092. Improvements relating to switches for electrical purposes. Bela Egger, 45, Southampton buildings, London.

APRIL 9, 1887.

5223. Improvements in holders for incandescent electric lamps. William Henry Bayley 2, Bernall-street, Woburn.

APRIL 19, 1887.

5707. Improvements in automatic cut-outs for electric arc lamps worked in series. Edward Frederick Hermann Harmsch Luerker and Henry Walter Kingston, 23, Southampton-buildings, Chancery-lane, London, W.C.

APRIL 25, 1887.

5972. A new and improved method of attaching telegraphic, telephonic or other insulators to bolts, spikes, and the like. Alexander Johnston, The Imperial Hotel, Dunfermline.

MAY 12, 1887.

6972. Apparatus for obtaining derived currents of variable intensity from a main electric current. John Clayton Newham, 169 Fleet street, London. (La Société Anonyme pour la Transmission de la Force par l'Electricité, France.)

SPECIFICATIONS PUBLISHED.

1887.

2130. Electrical inductors, &c. F. Jehl. 8d.

2134. Miners' safety lamps. A. Schanschieff. 8d.

CITY NOTES.

Electric Traction Company (Limited).—Registered by Ashurst, Morris, Crisp and Co., 6, Old Jewry, E.C., with a capital of £30,000 in 3,000 shares of £10 each. Object: to carry on the business of manufacturing and contractors for the supply of electrical power of all kinds, &c. The first subscribers are:

	Shares.
Viscount Dary, Quendon, Norfolk	1
Lord Egerton of Tatten, Knutsford	1
R. Macpherson, Willenden	1
Sir R. Abercromby, Bart., 17, Chandos-street, W.	1
F. W. J. Hubel, Malden-crescent, N.W.	1
J. Paxman, Colchester	1
A. A. C. Keppel, Eedes Hall, Norfolk	1

The first directors shall be appointed by the subscribers to the memorandum of association. The regulations contained in the table marked A in the first schedule of the Companies' Act, 1862, shall apply to this company with slight modifications.

Eclipse Electric Lighting Syndicate Limited.—Registered by Ernest Wood, 4, Broad Street, W.C., with a capital of £20,000 divided into 20,000 shares of £1 each. Object: to carry into effect an agreement dated February 4, 1888, and made between John Garford, of the one part, and W. Douglas Hamilton Tait, as trustee on behalf of the company, of the other part, to purchase and acquire the inventor's letters patent, &c., to carry on business as manufacturers and electric light company in all its branches. The first subscribers are:

	Shares.
J. Garford, 3, Vernon-chambers, W.C.	1
J. Robinson, 60, Gresham-street, E.C.	1
W. H. Foxes, Silverdale, Kent	1
W. C. Lee, Isleworth	1
H. Martyn, 68, Leadenhall-street, E.C.	1
H. E. Robinson, 11, Poultry, E.C.	1

The business of the company shall be managed by the board of directors, whose number shall not exceed nine nor be less than three. The first shall be Sir Charles Clifford, Bart., John Garford, Esq., and Valentine Robinson. The qualification of a director shall be the holding in his own right 200 shares of £1 each, and by way of remuneration they shall be paid for their services the sum of £150 per annum. The regulations of Table A in the first schedule to the Companies' Act 1862, do not apply to this company.

India Rubber, Gutta Percha, and Telegraph Works Company.—The report of this Company for the year ending December 31 states that the net profit amounted to £13,174, which, with the balance brought forward and deducting £20,800 paid on an interim dividend, leaves a disposable balance of £30,330. The directors recommend a dividend of 10s. per share, tax free, making with the interim dividend, a total payment for the year of 10 per cent. and leaving £9,530 to be carried forward. The Company it is stated, did an immense general business in the year; but competition and cost of raw materials also increased, and kept down the rate of profit on manufactured goods.

Telegraph Construction and Maintenance Company.—Subject to the audit of the accounts, the directors of the Telegraph Construction and Maintenance Company Limited, propose paying a dividend of 15 per cent. £1 16s. per share, in addition to the 5 per cent. already paid, making 20 per cent. for the year 1887.

Western Brazilian Company.—The traffic receipts of the Western and Brazilian Telegraph Company for the past week, after deducting the fifth of the gross receipts payable to the London Platino-Brazilian Company, were £2,550.

Brazilian Submarine Company.—The traffic receipts of the Brazilian Submarine Telegraph Company for the past week amounted to £3,856.

NOTES.

Telegraphic Money Orders. Mr. Heaton's proposal for telegraphic money orders will, it is said, shortly be put to a practical test.

A New Accumulator. It is stated that the firm of Rothschild has purchased the patent for a new accumulator devised by M. Laurent Cély.

The Electric Light in Sweden.—The town of Falun is shortly to be lighted with 50 arc lamps, of 1,200 c.p., and 300 incandescence lamps.

Train Signalling. A new electrical system of communication between guards and drivers of trains is about to be tried by the Metropolitan District Railway Company.

The Electric Telegraph in Spain.—The Administration of the Spanish Telegraphs will sell by auction on the 15th prox. the right to establish and work a telegraphic system in the town of Cordova.

Messrs. Woodhouse and Rawson. The factory for the manufacture of lamps and electrical apparatus established by this firm at Saint Nicolas d'Algermont, Seine Inférieure, has been in operation since the 1st inst.

The Electric Light in Bulgaria.—The Municipal Council of Sofia is considering the question of lighting this city by electricity. A prize of 5,000fr. will be awarded to the author of the best scheme of illumination, whether by gas or by electricity.

Laxton's Price Book.—This well known price book has reached its seventy-first edition. It contains several pages devoted to prices of apparatus connected with electric lighting, which will be useful to architects and others who have to estimate for such work.

Kensington.—The sub-committee of the Kensington Vestry have advised the Works Committee of that body to postpone a decision on the order sought by the Kensington Court Electric Light Company, in order to give rival companies time to present their plans.

The E.P.S. Accumulator.—The Electrical Power Storage Company have received information from Mr. W. H. Preece, F.R.S., that some of their E.P.S. cells for electric lighting have been in use at his house for two years without failure or expense, and look as good as new.

Postal Telegraphy.—The First Lord of the Treasury has written to Mr. Henniker Heaton, M.P., stating that the question of granting inquiry into the postal and telegraphic communication between England and all other parts of the Empire is under the consideration of the Cabinet.

Gas and Electricity in America.—According to the *Gaulet Journal*, there are 56 companies engaged in supplying electric light, and four were incorporated during the year. Four gas companies during the year were authorised to supply electric light, and three more have petitioned for similar permission.

Opposition to Telephone Bill.—At a meeting of the St. George's (Hanover-square) Vestry, last week, it was agreed to oppose the Bill which the United Telephone Company propose to introduce into Parliament. The Commissioners of Sewers also signed a petition against this Bill at the meeting on Tuesday last.

The Electric Light in Brussels.—The Thomson-Houston Company have written to a foreign contemporary

to point out that the incandescence lamps installed at the Molière theatre are not those of Edison, as was stated; but that the incandescence as well as the arc lamps throughout the theatre are those of the Thomson-Houston type.

The Electric Light at Brunswick.—A company has just been established at Brunswick for lighting a portion of the town by electricity, it is intended to include the ducal palace and the Court theatre in the radius of distribution. Several proposals on the part of foreign contractors are also under the consideration of the Communal Council.

The Abyssinian Expedition.—According to a telegram from Italy, relative to the Italian expedition at Massowah, the electric light machinery and apparatus sent out with the expedition has been taken to Saati, in order that the work of constructing the posts there may be carried on by night when the heat renders day labour unadvisable.

Faversham. The residence of W. J. Rigdon, Esq., M.F.H., has been fitted throughout with over 100 incandescence lamps, the system employed being that of Messrs. Laing, Wharton, and Down, and the fittings those of the artistic hammered coppered fittings usually connected with their name. The light has also been put into the brewery, offices, and private stables.

Wood Used in Telephony.—The S.S. "Gothenburg City" arrived at Antwerp on the 8th inst., from Newport News, Virginia, with 1,270 tons of walnut logs consigned to the Bell Telephone Manufacturing Company. This cargo of walnut, which is one of the largest ever brought to Europe, comprising no less than 1,828 logs, will be used entirely in the manufacture of telephone apparatus.

Primary Batteries.—A good word for a primary battery, as a means for electric illumination, has at length been spoken. During the Christmas festivals, the church of St. Clement at Prague was lit up by means of a primary battery; and the experiment is considered to be so satisfactory that it is intended to establish a permanent installation on the same basis. No details are given as to the precise nature of the battery.

Provisional Orders.—Mr. Barclay, in the House of Commons on Thursday, asked in how many cases the powers obtained by Provisional orders under the Electric Lighting Act of 1882 have been actually exercised; why so little progress had been made with electric lighting under the Act of 1882; and whether the Government intends to amend the Act, with the view of encouraging the development of electric lighting.

The Electric Light at Vienna.—The *Allgemeine Elektrizitäts* of Berlin has established a branch establishment at Vienna, where it is negotiating with the Imperial Gas Association for the purchase of its premises in the Schenkenstrasse and of the installation at the opera. The exhibition which will shortly take place on the Prater will be illuminated by electricity; the motive power for this installation is estimated at 600 h.p.

The Electric Light in Rome.—The gas company of Rome is energetically developing the central station for distributing the electric light which it has established in that city by means of the Zipernowski transformers. A capital of more than two millions of francs has already been expended in this enterprise. This, however, is considerably below the expenditure of three and a half millions made at Vienna by the Continental and Imperial Gas Company.

dynamo machine by a four horse-power gas engine. The installation was carried out by the Maxim-Weston Company, under the direction of Mr. Thomas Floyd, of Victoria Mansions. The premises are capably illuminated.

Intercolonial Postal Conference. Arrangements are made for holding an Intercolonial Postal and Telegraphic Conference in Sydney, as it is felt that the Colonies might be in greater harmony upon these subjects than they are. In the matter of telegraphy alone there is room for much improvement, especially as between New Zealand and the Australian group of Colonies in the matter of press telegrams. As it is, these are few and far between, and the result is that New Zealand loses that publicity in respect to its social, industrial, and political concerns which the press of Australia might give it, by reason of its more frequent intercommunication with Europe, if the New Zealand telegraphic rates were not so high. The subjects for discussion are the Ocean Mail Service question in its various phases, the New Zealand Cable and Pacific Mail Service questions, as well as any others relating to postal or telegraphic matters which any delegate may desire to bring forward. The Victorian Ministry arranged at a Cabinet meeting on January 5 to decline specific action respecting the subsidy to the Pacific cable project until the proposed Postal Conference in Sydney has sat and completed its business.

Effects of Current on Wine.—From the *Journal* of the Chemical Society we gather that F. Mengarini has continued the investigations of Blaserna and Carpine, who have shown that wine is artificially matured by the action of a current. In Mengarini's paper some further experiments on this subject are described, in which a current of 3.99 amperes per hour was passed for various periods of time through a sample of Italian wine; analyses were made of the wine without and with passage of the current and the results compared. The platinum electrodes were found to be covered with albuminous substances, blackened by oxidation; there was also a considerable deposit of these substances. The proportion of alcohol was diminished partly by the slight concomitant formation of acetic acid, partly also by evaporation, and partly also by its destruction by a more profound oxidation. There was also imparted to the wine a perfume similar to that acquired by maturing; this increased by prolongation of the current. The passage of the current also assists its future preservation. The colouring matters are affected, but the author would not for the present draw any conclusions from his experiments. If by passage of an electric current the wine could be sterilised, so as to effect the complete removal of *Bacterium aceti*, this process would be of considerable technical importance.

Central Electrical Laboratory.—The inauguration of this establishment, created by the International Society of Electricians, and provisionally installed at *place St. Charles*, Grenelle, recently took place under the presidency of M. Mascart. Amongst those present were M. Coulon, the director of posts and telegraphs, and many deputies, municipal councillors, engineers, electricians, and manufacturers. The interest arising from the sum of 300,000fr., constituting the balance left from the Electrical Exhibition of 1881, has been appropriated to the support of the laboratory in question. In the first room are placed the prime motors—a Weyher and Richmond locomobile of 20 h.p., and a Lenoir gas engine of 12 h.p.—working the dynamo machines of Edison, Gramme, and Sautter-Lemon-

nier. The illuminating apparatus comprises 5 Cance lamps, 2 Jablochhoff bougies, and 60 Edison incandescence lamps. In a second room are neatly arranged the various photometric apparatus; in proximity to which is a large chemical laboratory for the study of accumulators and primary batteries. Beyond is the room for obtaining measurements in absolute units, and, lastly, a room in which measurements are made in practical units for industrial purposes. The main subjects for investigation will be the efficiency of machines, the mechanical and electrical properties of cables and other conductors, and the calibration of instruments. Students will also be initiated in electrical measurements and other practical work.

A New Telephone Company. According to a Chicago paper, a new telephone company in Chicago, to compete with the Bell monopoly, will soon be an assured fact, provided the City Council looks favourably upon the scheme. The undertaking in question, the Cushman Company, is under the presidency of City Treasurer Plantz, and purposes to furnish a telephone service at 80 dollars per annum. One of the officers of the proposed company, in reply to questions, said:—"Dr. Cushman, who invented our instrument, made the first telephone, away back in 1851. He was then making a telegraph line from Racine to Beloit, Wis., and discovered the telephone principle by accident. In making a lightning arrester he placed the box, with the wire connections, in a swamp, and 16 miles further on put up another. One day he chanced to get his ear close to the box, and was astonished to hear the croaking of frogs in the swamp, sixteen miles away. He then began experiments over the wire, and the result was what he called a 'talking box.' The device was used for several years by different parties, and that is the reason we claim that the Bell Company has no right to their patent. Bell's invention of 1875 was the talking-machine of 1851. You talked into and received from the same box. It was the transmitter—which was not invented by either Bell or Cushman—that made the telephone. We are the only fighting competitors of the Bell Company, and we went down to Indiana and went at them boldly."

Austria.—The motive power required for the Jubilee Exhibition at Vienna, says *Industries*, was at first estimated at 450 h.p., afterwards at 600 h.p., and now it is reckoned that it will reach 1,000 h.p. The lighting of the fountains, which it is proposed to effect in the same manner as at the exhibitions in London and Manchester, has not been included in this estimate. The number of applications from persons wishing to exhibit is considerably higher than was anticipated. The Town Council of Stockerau are at present divided in opinion as to the advisability of using gas or the electric light. Sixteen councillors are in favour of the adoption of gas, and twelve advocate the employment of electricity. It has been decided to adopt gas for lighting purposes; but the necessary money for the carrying out of the project has not been granted, since the consent of more than sixteen councillors must be obtained before the money can be spent. The partisans of electricity still hope to prevail on the majority, so that the electric light may be eventually installed. In some spinning mills in the Erzgebirge the electric light has been installed. On winter mornings artificial light has to be used till 10 a.m., and in the afternoon from about 3.30 p.m. The glow lamp installation in the Court Theatre is progressing but slowly, and is not expected to be finished before the autumn. The Houses of Parliament are also to receive an electric light installa-

tion; the lighting will, however, be restricted to the legislative chambers and lobbies, the private rooms remaining lit by gas as heretofore.

Brussels Exhibition.—With reference to the subject of the note under this heading in our last issue, the following letter has been addressed by the Executive Committee to Count d'Oultremont, the Commissary-General of the Belgian section, in reply to the communication from "the Members of Committee 47."—"Monsieur the Commissary-General, Although the question brought to your notice by the Committee 47 of the Grand Concours is by no means within the province of that Committee, since it relates to an essentially private enterprise, we are anxious nevertheless to afford you every explanation and satisfaction in replying to the demand you addressed to us. The rumour, according to which the work of electric lighting is placed entirely in the hands of foreign firms, is absolutely erroneous. The national electrical industry will doubtless take a great part in the organisation of this service. This would be a natural consequence of the arrangements established by us up to the present date. Though it may be evidently desirable—as is observed by Committee 47—that all Belgian electricians should take part in the undertaking, it is also evident that the realisation of this wish must depend, in the first place, on the conditions offered by these electricians to the *Société du Grand Concours*. The statement relative to the letting of space in the Belgian electrical section bears also the impress of error. We know, in fact, that other firms besides the 'Société Industrielle' have applied for space in this section; and we know, moreover, that these firms have decided to occupy a vast area by reason of the important share conceded to them in our undertaking of the lighting. Please to accept, &c., (Signed) LEON SOMMER."

Electric Lighting in France.—According to the *Bulletin International de l'Electricité*, the central distributing station installed at Nancy by the Edison Company is a complete success, the working of the Zipernowsky transformers being very satisfactory. The importance of this fact would appear to be recognised by the gas interest; for a number of gentlemen connected with it have requested permission to visit the new works, which they did on the 16th inst., under the conduct of M. Chatard, the manager of the Edison Company. At Reims, on the other hand, the projects of electric lighting appear to have "passed into the domain of silence." Not only has the project of establishing a central station been, for the present at least, abandoned; but it is stated that all attempts to work the installation in the cellars of the Pommery premises have been relinquished. This can be due only to serious defects in this installation, and the fact illustrates the importance of entrusting such installations to competent hands.—The electric light is about to be introduced in the theatre at Béziers. Strange though it may sound to our ears, it is the gas company of that town which—following the lead of their *confrères* at Lyons—has undertaken to carry the installation into effect. We may well exclaim that "they manage these things better in France!"—At Montpellier the application of the gas company for a concession of the electric lighting has been refused, by reason of their stipulation that the rights at present vested in them should be prolonged for ten years. These rights being already secured to them for thirty years, the Municipal Council of Montpellier decided to accept the proposals of M. Popp rather than authorise an extension of the rights in question.

The Electric Light in Brussels.—The following details in relation to the electric lighting of the vast establishment of Hirsche at Brussels are given by the *Bulletin International*. The lighting comprises 300 incandescence lamps and 36 arc lamps. The latter are distributed at the entrance and on the ground floor, whilst the upper floors and offices, the underground workshops and the passages are illuminated by the former; the use of gas being entirely discontinued. The motive power consists of a steam engine of 80 h.p. effective, on the Walschaert's system, with multitubular boiler. This machine actuates two compound dynamos of the Boukaert type, each giving 110 volts and 175 amperes. The arc lamps are of the Piette and Krizic form, 26 of them being of 600 c.p., 8 of 1,000 c.p., and 2 of 1,400 c.p.; these last being placed at the entrance, where they are very conspicuous. The incandescence lamps, of the Swan type, are of 16 c.p. The lamps are alternately connected to the two dynamos; so that, in case of accident to one of them, there is but a partial extinction of the light. From the economical, as well as from other points of view, the lighting is a complete success. The cost of the gas annually consumed in the Hirsche establishment was 28,000fr.; whereas, from its owner's calculation, the cost of the electric lighting will not be above 13,000fr., in which sum is included the amortisation at the rate of 12½ per cent. of the capital expended in the installation. There will consequently be a saving of 15,000fr. per annum, which is the more remarkable from the fact that gas is comparatively very cheap in Brussels—viz., 15c. the cubic metre. The installation has been carried out by the firm of Bouckaert and Co., of Brussels.

Exeter.—At a public meeting held in the Victoria Hall, Exeter, on Tuesday, it was proposed and carried unanimously "that in view of the great satisfaction given in the lighting of Exeter streets by electricity, this meeting is of opinion that it would be to the interest of the city and add to its attractiveness and prosperity if the public streets were permanently lighted by the system of arc lighting now in use." Following on this proposition was another, which was also carried unanimously, "that it is the desire of this meeting that a local company should at once be formed for the purpose of supplying Exeter with the Thomson-Houston system of electric lighting for public and private use." These propositions were carried, after Mr. Wharton, of the firm of Laing, Wharton, and Down, had explained to the audience, which numbered some 2,000 persons, the present position of the electric light, sketching its method of production and its history, and suggesting that the best possible way for any town to obtain the electric light was to form a local company. He estimated the cost of arc lamps at about £20 each per annum, and the incandescent for domestic purposes at 4d. per hour, and stated that the electricity could be measured by meters as in the case of gas. A number of questions were asked of Mr. Wharton by various gentlemen in the room, which, as will be seen from the unanimous feeling of the meeting, were satisfactorily answered. Exeter is in a position to obtain the light upon more economical conditions than some other towns, as there is a large supply of water power now running to waste, and no doubt when a company is formed this will be utilised. As we have said before, we think that this is a right direction in which to work—namely, the formation of local companies quite capable of looking after their own interest and seeing that the work is properly and economically done.

ELEMENTARY TESTING SUITABLE FOR ELECTRIC LIGHTING SYSTEMS.

Resistance Boxes.—It is neither necessary nor practicable in these articles to describe the peculiarities of the boxes of resistances as supplied by different makers; but it seems desirable that the general principles of the construction of one or two of the more common forms should be described. The way in which the resistances are fixed in the box and connected to the contact plates outside the cover will be

FIG. 4.

readily understood by reference to Fig. 4. In this figure *b b b* represent three bobbins which may be taken as part of a series. The bobbins may be wood or vulcanite or other insulating material, or they may be made of metal, but in that case they should be split up one side to avoid induced currents in them when the current through the coil is made or broken. When the bobbins are metal they should be covered with thin rubber, or paper soaked in paraffin or spirit varnish, before the wire is wound on, so as to avoid any chance of contact between the wire and the bobbin. These bobbins are fixed to the cover, *c*, of the box, which should be of highly insulating material and is usually made of vulcanite. On the outside of the cover rows of brass or copper blocks, *a*, are fixed in some such manner as that indicated diagrammatically in Fig. 5. To the underside of each of these blocks two rods, *d, d*, are soldered, and they pass through the cover projecting to, or nearly to, the bottom of the bobbins. The wires forming the resis-

should be common to both; each coil should terminate at the brass block, and the blocks must have such a section that the resistance of the whole circuit of blocks between the terminals of the box is a very small fraction, it should be less than a thousandth, of the lowest resistance in the box. The reason for this will become apparent when we come to the adjustment of the separate coils to their proper value. The wire of which the coils are composed should be such as not to change readily with time, and its resistance should change as little with change of temperature as possible. One of the best substances for the purpose is an

FIG. 5.

alloy of two parts by weight of silver to one of platinum, but this has the disadvantage of being expensive. German silver is commonly used, and in the form recently introduced under the name of platinoid it promises to do well for the purpose. It is, however, doubtful whether sufficient constancy with time and uniformity of temperature variation can be obtained with this material. The wire should be well covered with silk, and the finished bobbin should be stored for some hours at a temperature of about 120deg C and then while hot immersed in melted paraffin, with which substance it should be thoroughly soaked. The paraffin should be pure and must be free from acid. The variation of the resistance of the wire with temperature introduces one of the greatest difficulties in the manufacture of perfectly reliable resistance boxes. The difficulty is mainly due to the fact that two different specimens of the same alloy seldom have the same temperature variation, and hence the coils of boxes which are adjusted to be correct at

FIG. 6.

tances are wound on these bobbins, and generally, though not necessarily, each resistance has a separate bobbin. The wire should be doubled on itself, the ends soldered to the rods *d, d*, and for convenience of adjustment the bend left on the outside as shown at *e*. The reason that the wire is doubled on itself is that a coil so wound has very little self-induction, and the more perfect the doubling, that is, the closer the two wires are kept to each other during the winding, the better. The rods *d* are introduced merely for convenience of manufacture; they should have very little resistance compared with the coil attached to them, or, if their resistance is a sensible fraction of that of the coil, the material of which they are made should be the same as that of the wire. It is important that both ends of each coil should have a separate rod connecting it to the brass block, as no part of the circuit of two successive coils

one temperature are seldom relatively correct at any other temperature. The temperature variation is found to depend not only on the composition of the metal, but also on its physical state as to hardness, annealing, and so forth. For this reason it is advisable to keep the wire heated for a day or two to a considerably higher temperature than that to which it is ever likely to be exposed in actual use, before it is standardised. The temperature variation of the different coils may be made equal by the introduction of such a length of wire having a high temperature variation, such as copper wire, into the different coils as is sufficient to raise their variations all to equality with that which varies most. The copper wire may either be introduced in series or in parallel with the other wire, but the series method is the simpler. It can be readily introduced near the bend, where the wire is doubled, after the coil is wound, or the

temperature variation of the wire may be determined to begin with, and the proper length of copper wire to bring the variation to a standard amount introduced in the interior of the coil. The coils are cut out of the circuit by means of brass plugs, *f*, as indicated in the figure, and one of the greatest defects of this arrangement lies in the fact that when only a few of the coils are required a large number of contact joints are included in the circuit, each one of which, and their sum, is assumed to have zero resistance. The vertical holes between the blocks are not easily cleaned, and hence the contacts between the plugs and blocks are apt to be imperfect, giving rise to error in the measurement. Perhaps the most satisfactory method of cleaning the holes is to wash them by means of a rod covered with cloth soaked in paraffin oil, and then dry them thoroughly with a dry cloth. They should never on any account be rubbed with glass or emery paper, as the fine glass or emery sinks into the surface of the metal and grinds the plug, at the same time preventing perfect contact. If washing will not do, the holes should be scraped with a round-pointed scraper. The same remarks apply to the cleaning of the plugs; they should be washed clean and, if that is not sufficient, they should be scraped clean but not papered.

A convenient arrangement for a set of resistances from one to ten thousand ohms, combined with two sets of ten, one hundred, and one thousand ohms, designed to form three sides of the Wheatstone's bridge arrangement, is shown in diagrammatic form in Fig. 5. The connections of the battery and galvanometer circuits are also indicated. The resistance to be measured is placed between the terminals *t*, and the terminals *t*₁ *t*₁ short circuited by a plug. The resistances of the sides *a* and *b* of the diagram, Fig. 3, are supposed equal in this case, and each of them 100 ohms, while the resistance *R* is supposed to have been balanced by 3,422 ohms, forming the side *d* of Fig. 3. The resistance of *R* would in such a case be 3,422 ohms since *a* and *b* are equal.

Another, and in some respects considerably better, form of resistance box is shown in plan in Fig. 6. In this form the brass blocks to which the ends of the resistances are attached are arranged in circles with a single circular block in the centre. The way in which the resistances are joined up is shown by dotted lines between the blocks. There are ten blocks in each circle and they serve to join nine equal resistances in series, the first and last block of each set being insulated from each other. The terminal *t* is joined inside the box by a thick rod of copper to the central block of the thousands circle, the block marked 0 of that circle is in a similar manner joined to the central block of the hundreds circle, and so on as indicated by the dotted lines in the figure, the block marked 0 of the tenths circle being joined to the terminal *t*₁. Two flat stout strips of copper, *c*, *c*, serve to join the terminals *t* to *t*₂, or *t*₁ to *t*₂, as may be desired. In front of the circles of blocks and joining *t*₁ and *t*₂ there is a straight row of blocks forming the terminals of two sets of resistances usually of the number of ohms marked in the figure. The box thus gives in a convenient form three of the sets of resistances required in the Wheatstone bridge arrangement. The terminals *t* and *t*₂ may be joined by the bar *c*, and the resistance to be measured introduced between *t*₁ and *t*₂, the bar being left out of contact with *t*₂, as shown in the figure, or *t*₁ and *t*₂ may be joined, and *t* insulated from *t*₂, and the resistance to be measured introduced at that end. In this arrangement one plug only is necessary for each circle. When the plug is placed in the hole between the block marked 0 and the central block there is no resistance in that circle when it is placed between the block marked 1 and the central block, the resistance introduced is $\frac{1}{10}$, 1, 10, 100, or 1000, according to the circle used, and similarly for the other numbers. Thus if the blackened circles are taken to represent the positions of the plugs the resistance between the terminals *t* and *t*₁ is 2471.0. The advantage of this arrangement is the small number of plugs required, and hence the correspondingly smaller chance of error due to resistance in their contacts. There are of course a considerably greater number of blocks required for the same resistances and a correspondingly greater number of resistances than in the form shown in Fig. 5. This causes greater expense in

manufacture, arising chiefly from the greater number of separate resistances which have to be adjusted. The battery and galvanometer circuits should be joined up in a similar manner to that indicated in Fig. 5. As a general rule it is preferable to join the battery between the terminals *t*₂ and *t*₃, and the galvanometer between the terminal *t*₁ and *t* or *t*₂, according to the end of the box at which the resistance to be tested is inserted. The pair of resistances which it is best to use in the two front sets has of course to be determined, for the particular case under consideration, by the rules given above.

(To be continued.)

A SIMPLE METHOD OF TREATING PROBLEMS CONNECTED WITH NETWORKS OF CONDUCTORS.*

BY W. E. SUMPNER, B.S.C.

(The italic letters throughout the formulae in this article have inadvertently been raised, and represent suffixes.)

Those who have taken the trouble to work out many problems connected with networks of conductors know very well how cumbrous are the expressions with which they have to deal. If determinants are not readily handled, a great deal of perseverance is required to arrive at the solution of any but the simplest problems, while even if they are constantly used the expressions obtained are still very complex—they seem mere mathematical abstractions, and appear to have no physical meaning. In all practical cases, moreover, the solution is of a simple kind, however complex the working may be; and as it is natural to suppose that whenever the solution of a problem is simple there must be some simple means of getting to it, it seems very reasonable to believe that in most cases there must exist some quicker and simpler method of solution than that usually employed.

Now, if in any given network of conductors we work out the relation connecting the current flowing in any one branch with the values of the electromotive forces acting in the various branches we always find the following result. If only one electromotive force is acting the current is proportional to the electromotive force. If there are two electromotive forces acting the current is the sum of two quantities, each of which is proportional to one electromotive force, and is independent of the other. In short, we always find

$$C_x = K_a E_a + K_b E_b + K_c E_c + \dots$$

Where C_x is the value of the current flowing in the branch of the network denoted by the letter *x*, where $E_a E_b E_c \dots$ are the electromotive forces acting in the branches denoted respectively by the letters *a, b, c, \dots* and where $K_a K_b K_c \dots$ are certain quantities depending only on the resistances of the different branches of the network. The above equation is only the mathematical way of making the statement that the current produced in any given branch by the combined agency of several electromotive forces is always the sum of the currents which would be produced in that branch by each electromotive force acting separately.

The truth of the equation is easily established when it is remembered that the current can only depend on the electromotive forces and resistances; that it is of the nature of an electromotive force divided by a resistance; that it cannot be made infinite by diminishing any one electromotive force to zero, and that it must be zero when no electromotive forces are acting.

If C_x depended partly on a quantity which was inversely proportional to one of the electromotive forces, it would become infinite when this was made very small. If it depended partly on a quantity which was proportional to the product of two or more electromotive forces, it could not be of the nature of an electromotive force divided by a resistance. C_x can, therefore, only be made up of terms, each of which is proportional to an electromotive force, and to this one only.

The quantities, *K*, in the above equation, depend only on the resistance of the branches. If we knew what were

* Paper read before the City and Guilds of London Institute Old Students' Association, Feb. 22, 1888.

their values we should know the solution of any given problem. Let us, for the present, assume that we know them; and let us denote by the symbol R_{xz} the ratio between an electromotive force, E_x , placed in the branch, x of the network to the current, C_g , in the branch g , produced by this electromotive force.

Then, if E_x is the only E.M.F. in the network, we have for the current in the branch g

$$C_g = \frac{E_x}{R_{xz}}$$

and if there are many electromotive forces we have

$$C_g = \frac{E_x}{R_{xz}} + \frac{E_y}{R_{yg}} + \frac{E_z}{R_{zg}} + \dots$$

The currents and electromotive forces have direction, and, consequently, R_{xy} may be sometimes a positive quantity, and sometimes a negative one. If we choose at will a direction in each branch as the positive direction, and consider the current or electromotive force in that branch as positive when acting in the positive direction of the branch, then R_{xy} will be positive or negative, according as a positive E.M.F. in the branch x produces a positive or negative current in the branch y .

The quantities R_{xy} are generally very complex quantities. They are all of the nature of resistances, and may be called resistance ratios. Although the solution of any problem can easily be expressed in terms of them, it does not necessarily follow that it is needful to calculate all or any of them in order to solve any given problem. Most practical problems have very simple solutions, while the resistance ratios are nearly always very complex quantities. It must therefore be possible in most cases to eliminate them from the solution without actually calculating them out. It consequently seems more important to find out relations between these quantities than to express them directly in terms of the resistances of the different branches of the network.

One of the most important properties of these ratios is that

$$\frac{R_{xy}}{R_{xz}} \text{ is independent of } x \dots (1)$$

where the resistance of the branch x is denoted by x . Suppose the only E.M.F. in the network is that in the branch x . The value of C_y , the current produced in the branch y , will be directly proportional to the value of C_x , the current in the branch x . It will be, moreover, independent of x because it will be always possible to find out the value of C_y without knowing what x is. Now in this case

$$C_x = \frac{E_x}{R_{xx}} \quad \text{and} \quad C_y = \frac{E_x}{R_{xy}} \quad C_z = \frac{E_x}{R_{xz}}$$

From this it follows that $\frac{R_{xy}}{R_{xx}}$ and $\frac{R_{yz}}{R_{xz}}$ are independent of x .

Now, if we denote by R_x the resistance of the network between the extremities of the branch x (supposing the branch x removed) it is easy to see that the value of C_x , the current in x produced by the electromotive force E_x , is

$$\frac{E_x}{x + R_x}$$

but it is also $\frac{E_x}{R_{xx}}$ by our definition of R_{xx} . We accordingly have

$$R_{xx} = x + R_x \dots (2)$$

and R_{xx} may be called the resistance of the x circuit.

We must not assume that R_{xy} and R_{yx} are the same. The first is the ratio between an E.M.F. in the branch x to the current produced by it in the branch y ; the second is the ratio between an E.M.F. in the branch y to the current produced by it in the branch x . It is easy to see, however, that $\frac{R_{yx}}{R_{xx}}$ is independent of x .

Suppose there are two electromotive forces, E_x E_y , in the network, such that they tend to send currents in opposite directions through the branch x . We then have

$$C_x = \frac{E_x}{R_x} - \frac{E_y}{R_{yx}}$$

Suppose the values of E_x and E_y so adjusted that current C_x is zero, then

$$\frac{R_{yx}}{R_{xx}} = \frac{E_y}{E_x}$$

But if the current in the branch x is zero, we the resistance x to any extent without causing to flow through the branch x . As we have either of the electromotive forces by this process that the new value of the ratio $\frac{R_{yx}}{R_{xx}}$ must be equal old ratio, or

$$\frac{R_{yx}}{R_{xx}} \text{ and } \frac{R_{yz}}{R_{xz}} \text{ are independent of } x$$

We have in any network of conductors

$$C_g = \frac{E_g}{R_{gg}} + \sum \frac{E_x}{R_{xg}}$$

where E_g is the current produced by the E.M.F. R_{gg} the branch g , and where $\sum \frac{E_x}{R_{xg}}$ denotes the sum of the currents due to the electromotive forces outside the branch g .

This equation may be written

$$C_g = \frac{E_g}{R_{gg}} + \frac{1}{R_{gg}} \sum R_{xg} E_x = \frac{K + E_g}{R_{gg}}$$

where

$$K = \sum \frac{R_{xg} E_x}{R_{gg}}$$

and is independent of g and E_g by (1). K is a constant electromotive force which, when placed in the branch g , produces in that branch the same current as the electromotive forces outside the branch g produce. It is important to notice that it is a constant for alterations in the value of the branch and in the E.M.F. E_g .

Now, suppose we alter both the value of s and the value of g such a way

$$E'_g - E_g = (g' - g) C_g$$

where the dashed letters refer to the new values we have

$$C_g = \frac{K + E_g}{R_{gg}} = \frac{E'_g - E_g}{g' - g}$$

From this we obtain by addition

$$C_g = \frac{K + E_g}{R_{gg} + g' - g}$$

Now $R_{gg} = g + R_g$ by (2).

Hence

$$R_{gg} + g' - g = g + R_g = R'_g$$

and $C_g = \frac{K + E_g}{R'_g} = C'_g$ by definition, or the new current C_g is the same as the old value.

5. This means that if C_g be the current in any network of conductors, and if the resistance of the branch be changed to g' the currents in every branch of the network will be the same as before, provided an additional electromotive force be inserted in the branch g the current and equal in amount to $(g' - g) C_g$.

We may easily prove the matter in another way as follows:—

If $PQRS$ be a wire through which a current C flows, the difference of potential between the points Q and S will be C_r if r is the resistance of the wire between the points Q and S , and if there is no E.M.F. between the points Q and S . Otherwise it will be $C_r - E$ where E is the E.M.F.

the two points. By choosing the position of the point S, so that $C r = E$, the points Q and S will be at the same potential and may be joined by a wire of any resistance whatever without altering the current flowing either in the wire P R T, or that through any other wire in connection with it. If the resistance of the wire joining Q and S be zero, this will still be true. But in this case we practically have removed the resistance r and the E.M.F., E , from the network without changing the current in any branch by the process.

We may put this statement into mathematical language as follows:—

We have, if E_y is the only E.M.F. in the network,

$$C_x = \frac{E_y}{R_{yx}} \text{ and } C_z = \frac{E_y}{R_{yz}}$$

Now alter the resistance of one of the branches z to z' , and at the same time insert an E.M.F. in the branch z equal to $(z' - z) C_z$.

The new value of C_x will be

$$\frac{E_y}{R'_{yx}} + \frac{(z' - z) C_z}{R'_{zx}} = \frac{E_y}{R'_{yx}} + \frac{z' - z}{R'_{zx}} \frac{E_y}{R_{yz}}$$

where the dashed quantities are what the corresponding undashed quantities become when z' is put for z .

But by (5) the new value of C_x is equal to the old value:

$$\frac{E_y}{R_{yx}} = \frac{E_y}{R'_{yx}} + \frac{z' - z}{R'_{zx}} \frac{E_y}{R_{yz}}$$

or, dividing out by E_y , we have

$$\frac{1}{R_{yx}} = \frac{1}{R'_{yx}} + \frac{z' - z}{R'_{zx} R_{yz}} \quad \dots (6)$$

Where x, y, z are any three branches of the network (any two or all three of which may be the same).

From (6) we have by interchanging y and x

$$\frac{1}{R_{xy}} - \frac{1}{R'_{xy}} = \frac{z' - z}{R'_{zx} R_{zy}} \\ \frac{1}{R_{yz}} - \frac{1}{R'_{yz}} = \frac{z' - z}{R'_{zx} R_{zy}}$$

By division we obtain

$$\frac{\frac{1}{R_{xy}} - \frac{1}{R'_{xy}}}{\frac{1}{R_{yz}} - \frac{1}{R'_{yz}}} = \frac{R_{yz} R_{zx}}{R_{zy} R_{zx}} \quad \dots (7)$$

Now, by (3) the right hand side of this equation is independent of both z and z' . The left hand side must, therefore, also be independent of z and z' .

This can only be if $\frac{R_{yz}}{R_{xy}}$ is independent of z , where z is

the resistance of any branch of the network whatever. Now, since the ratios R_{xy} depend only on the resistances of the network branches, and since R_{xy}/R_{yz} is independent of the resistance of any branch, the ratio must be a simple number, which, from symmetry, must be either $+1$ or -1 . A reference to equation (7) shows that it must be the positive quantity.

For suppose $\frac{R_{xy}}{R_{yz}} = a = \frac{R_{yx}}{R_{zy}}$ by symmetry then from

$$(7) - \frac{a \left(\frac{1}{R_{yx}} - \frac{1}{R'_{yx}} \right)}{\left(\frac{1}{R_{yz}} - \frac{1}{R'_{yz}} \right)} = \frac{R_{yz} R_{zx}}{R_{zy} R_{zx}} = \frac{R_{yz}}{R_{zy}} \cdot \frac{R_{zx}}{R_{zx}} = a^2, \\ \text{or } a = a^2, \quad \text{or } a = +1.$$

We accordingly have the very important property due to Clerk Maxwell.

$$R_{xy} = R_{yx} \quad \dots (8)$$

or the current in the branch y produced by an E.M.F. in the branch x is exactly equal to the current in the branch x produced by the same E.M.F. in the branch y .

We have in general

$$C_g = \frac{E_b}{R_{bg}} + \sum \frac{E_x}{R_{xg}}$$

Suppose the resistances of the branches of the network are so arranged that an E.M.F. E_b in the branch b produced

no effect in the branch g . In this case the branches b and g are said to be conjugate. The current in g produced by the E.M.F. E_b is E_b/R_{bg} . But this is zero. Hence

R_{bg} is infinite when the branches b and g are conjugate $\dots (9)$

But if an E.M.F. in b produces no effect in the branch g its alteration will not produce any effect. Now a given alteration of E.M.F. is always equivalent to a certain alteration of resistance by (5). Hence an alteration of the resistance b will produce no change in the current C_g .

$$\text{Now } C_g = \sum \frac{E_x}{R_{xg}}$$

and this is independent of b whatever the relative values of the electromotive forces, provided only that the branches b and g are conjugate. This can only be the case if

R_{xg} is independent of b when the branches b and g are conjugate $\dots (10)$

This is another way of putting the general statement of Dr. Frolich, that if two branches are conjugate the current in one is unaltered by closing or unclosing the circuit of the other branch, however many electromotive forces may be acting in the rest of the network.

We may illustrate some of the above properties by applying them to a few simple problems.

To find the most sensitive galvanometer to use under given circumstances.

The current through the galvanometer at any moment will be by (4) equal to

$$\frac{K + E_g}{R_g + g}$$

This will produce a deflection $\frac{S}{g + R_g} (K + E_g)$

where S is the deflection given by a unit current. If we alter the galvanometer we shall change S and g , but nothing besides, and the best galvanometer we can use is that which will make

$$\frac{S}{g + R_g} \text{ a maximum.}$$

It will therefore depend on the resistance R_g , which is external to the galvanometer. We may, in fact, compare a galvanometer to a battery. The latter has a given E.M.F. and internal resistance; the former has a given sensibility and internal resistance. In choosing a battery for any purpose, we have to consider its two constants with reference to the external resistance it is to be used with, and in choosing a galvanometer we have exactly similar considerations to deal with.

For galvanometers of the same kind wound with coils of the same size, where the only difference is in the diameter of the wire wound on the bobbins, we may assume S varies as \sqrt{g} , and in this case the value of $\frac{S}{g + R_g}$ will be a maximum when $g = R_g$; or we must choose a galvanometer of resistance equal to that of the external resistance of the

galvanometer circuit. Thus, in a Wheatstone's bridge, when balanced, where

$$R_g = \frac{(g + s)(p + r)}{g + s + p + r},$$

the galvanometer should have a resistance equal to the parallel resistance of the branch circuit connecting the terminals of the galvanometer.

If the galvanometer be a Thomson galvanometer with four coils of approximately equal resistances, we can, by

different arrangements of the coils in series or in parallel, alter the resistance of the galvanometer in the ratios 1:4:16, while the sensibility is simultaneously increased in the ratios 1:2:4. Thus, if the four coils together have a resistance of 10,000 ohms, we can, by putting two pairs of coils in parallel, diminish the resistance of the galvanometer to 2,500 ohms, while the sensibility will be reduced to one-half its previous value. The value of $\frac{S}{g+Rg}$ will increase if Rg is less than 2,500. Similarly we can, by putting all four coils in parallel, diminish the resistance of the galvanometer to 625 ohms.

Maxwell's Method of determining Self-Induction.

If in one of the arms s of the bridge be placed a coil of wire having a coefficient of self-induction L , then while the current Cs is changing, there is an additional electromotive force acting in the branch s of amount equal to

$$L \frac{dCs}{dt}$$

The current through the galvanometer will accordingly be

$$Cg = \frac{Eb}{R\delta g} - \frac{L \frac{dCs}{dt}}{Rsg}$$

If the bridge is balanced for steady currents, $R\delta g =$ infinity, and $Cg = -\frac{L \frac{dCs}{dt}}{Rsg}$.

The quantity flowing through the galvanometer while the current is established will be

$$Q = \frac{LCs}{Rsg};$$

and this will produce a swing θ , which, by the formula for the ballistic galvanometer, will be related to Q according to the equation

$$Q = \frac{H}{G} \frac{\tau}{\pi} \sin \frac{1}{2} \theta,$$

τ being the period of the galvanometer, and H and G being constants.

If, now, we alter the resistance of the branch s by an amount σ , and observe the steady current through the galvanometer we know by (5) that this current is exactly the same as would be produced by an extra electromotive force, σCs , acting in the branch s .

The current produced by this will be

$$Cg = \frac{\sigma Cs}{Rsg},$$

and this will produce a steady deflection, α , according to the equation

$$Cg = \frac{H}{G} \tan \alpha.$$

By division we obtain

$$\frac{Q}{Cg} = \frac{\tau \sin \frac{1}{2} \theta}{\pi \tan \alpha} = \frac{L}{\sigma}$$

or

$$L = \sigma \frac{\tau \sin \frac{1}{2} \theta}{\pi \tan \alpha}.$$

In Ayrton and Perry's method the discharge Q takes place n times per second, producing a current nQ , which is balanced by making the current due to the derangement σ equal and opposite to it. This will happen when

$$n \times \frac{LCs}{Rsg} = Cg = \frac{\sigma Cs}{Rsg}$$

$$\text{or } L = \frac{\sigma}{n}.$$

In Prof. Silvanus Thompson's modification of Joubert's method of determining self-induction the galvanometer and battery circuits are always closed, and an alternating electromotive force is inserted into the battery circuit by means of an induction coil. In this case we have

$$Cg = \frac{Eb}{R\delta g} - \frac{L \frac{dCs}{dt}}{Rsg}$$

$$Cs = \frac{Eb}{R\delta s} - \frac{L \frac{dCs}{dt}}{Rss}$$

These two equations are sufficient to determine the solution when $E\delta$ is given. We may assume that if there are n alternations per second

$$E\delta = E \sin 2\pi nt,$$

where E is the maximum value of the E.M.F.

By solving the two simultaneous differential equations, and determining the condition that the mean square of the current through the galvanometer branch shall be a minimum, it may be shown that

$$2\pi nL = \sqrt{\sigma Rss},$$

where σ is the apparent alteration of the resistance of the branch s for steady and alternating electromotive forces in the battery circuit.

In problems involving alternating currents contractions similar to those used above have necessarily to be used in order to save time. The advantage of using the resistance ratios consists in the fact that they are the most natural ones to use; they have a simple physical meaning; and in practical cases their values can always be approximately obtained by mere inspection of the network, in much the same way as the walking distance between two places in London can be guessed at by inspection of a street map.

JUVENILE LECTURES.

BY W. H. PREECE, F.R.S.

(Concluded from page 155.)

The next purpose that electricity is used for, to which I want to draw your attention, is that of the transmission or propulsion of coaches on railways. I have taken the trouble to find out the various railways and tramways in America, in Great Britain, and on the Continent, that are now worked by means of electric currents. Here is a list of them:—

ELECTRIC TRAMWAYS IN AMERICA.

The American *Electrician* and *Electrical Engineer* gives the following list of electrically worked tram lines now in actual operation in the United States:—

Appleton, Wis., Appleton Electric Street Railway, overhead, 4½ miles, Van Depoele's system, 5 motor cars.
 Ashbury Park, N.J., Lea Shore Electric Railway, overhead, 4 miles, Daft.
 Baltimore, Md., Union Passenger Railway Company, overhead, Daft.
 Bellevue, Pa., 4 miles.
 Binghamton, N.Y., Washington Street and State Asylum Electric Railroad, overhead, 5½ miles, Van Depoele.
 Denver, Col., Denver Tramway Company, conduit, 4 miles, Short-Nessmith, series.
 Detroit, Mich., Detroit Electric Railway Company, overhead, 2 miles, Van Depoele, 4 motor cars.
 Detroit, Mich., Highland Park Railway Company, overhead, 3 miles, Van Depoele, 2 motor cars.
 Gratiot, Mich., Gratiot Electric Railway Company, overhead, Van Depoele, 1 motor car.
 Ithaca, N.Y., Ithaca Street Railway Company, overhead, Daft.
 Kansas City, Mo., Kansas City Electric Railway Company, Henry.
 Lima, O., Lima Street Railway Motor and Power Company, overhead, 6½ miles, Van Depoele, 7 motor cars.
 Los Angeles, Cal., Los Angeles Electric Railway Company, overhead, 5 miles, Daft, 4 motor cars.
 Mansfield, O., overhead, Daft.
 Montgomery, Ala., Capital City Electric Street Railway Company, overhead, 11 miles, Van Depoele, 20 motor cars.
 Port Huron, Mich., Port Huron Electric Railway Company, overhead, 2½ miles, Van Depoele, 3 motor cars.
 Richmond, Va., Richmond Union Passenger Railway, overhead, Sprague motors.
 St. Catherine's, Ont., overhead, 6 miles, Van Depoele.
 Scranton, Pa., Scranton Suburban Railway Company, overhead, 2½ miles, Van Depoele, 3 motor cars.
 Wichita, Kan., Wichita Riverside and Suburban Railway Company, overhead, 4 miles, Van Depoele, 6 motor cars.
 Windsor, Can., Windsor and Walkerville Electric Railway Company, overhead, 1½ miles, Van Depoele, 1 motor car.
 Woonsocket, R. I., Woonsocket Street Railway Company, overhead.

ELECTRIC TRAMWAYS ON THE CONTINENT.

Amsterdam, Cortverloren Park, overhead, ¼ mile, Siemen's system, steam.
 Berlin, Lichterfelde (Berlin-Anhalt Railway), rails, 1½ mile, Siemens.
 Brussels, tramways, accumulators (Julian), steam.
 Charlottenburg, Spandauer Beck, overhead, Siemens, steam.
 Cologne, tramways, E.P.S. accumulators (Huber).
 Frankfurt-on-Maine, Frankfurt to Offenbach Railway, overhead, 4½ miles, Siemens, steam.

Hamburg, tramways, E.P.S. accumulators (Huber).
 Hohenzollern-Hohenzollern Colliery (Upper Silesia), overhead, $\frac{1}{2}$ mile, Siemens, steam.
 Vienna, Maching Hinterbrühl (Austrian Southern Railway), overhead, 2.8 mile, Siemens, steam.
 Zankerode, Zankerode Mines, Saxony, overhead, $\frac{1}{2}$ mile, Siemens, steam.

ELECTRIC TRAMWAYS IN GREAT BRITAIN.

Blackpool, Blackpool Tramway, buried central rail, 2 miles, Holroyd Smith's system, steam.
 Brighton, Brighton Beach, rails, 1 mile, Volk, gas.
 Brighton, Brighton and Shoreham Tramway, 4 miles, Electric Traction Syndicate accumulators, steam.
 Glynde, Glynde (Clay Pits, open, 1 mile, telpherage, steam.
 London, North Metropolitan Tramways (Stratford and Manor Park), 4 miles, Edison accumulators, steam.
 Newry, Bessbrook and Newry, raised central rail, $\frac{3}{4}$ miles, Hopkinson, water.
 Portrush, Portrush and Bushmills, raised side rail, 6 miles, Siemens, water.
 Ryde, I.W., Ryde Pier, rails, $\frac{1}{2}$ mile, Siemens, gas.

You will see how greatly and how rapidly this great power that electricity gives us is being utilised for useful purposes. One of the earliest lines upon which the power was used was the Portrush and Bushmills Railway in Ireland. But the most complete and most perfect railway of its kind has lately been carried out by Dr. Edward Hopkinson, Sir William Siemens's assistant in carrying out the Portrush Railway. I refer to the Bessbrook and Newry Electric Railway.

Another application of electrical power tried at the Paris Electrical Exhibition was carried out by M. Tissandier, who attempted to navigate a balloon by its means. The balloon worked satisfactorily inside the exhibition building, but failed when tried in the open air.

A very curious departure from the ordinary practice of conveying materials was started by Professor Fleeming Jenkin, who is, unfortunately, now no more, and he, in conjunction with Professors Ayrton and Perry, started a system called telpherage. Not far from Lewes, a mile or mile and a quarter from the Glynde railway station, in the Downs, there are certain clays which are valuable, and from the clay pits the clay is sent down to Newhaven for shipment abroad. This system of telpherage carries the clay from the pits to the station by means of electricity. Two heavy wires are fixed on cross-beams, or posts, which pass over the meadows, they do not interfere with the roads or the grazing of cattle, they pass over bogs, marshes, rivers, and anywhere you like, and on these wires skeps—a kind of bucket—are carried on rollers, by which they pass along. Each skep carries about half a hundred-weight of stuff. The arrangement is extremely ingenious, and daily and hourly trains pass by this means over the Downs to Glynde Railway Station carrying the clay. Such is the telpherage system.

But there is one system of carriage where electricity is destined to become more useful and more valuable than any other that I have brought before you, and that is in the working of a system of tramways in towns. There are few people who know that the number of horses required to work a tramway is 12 per car. My figures are taken from Manchester, where there is one of the best worked systems of tramways that we have in this country. There every car requires 12 horses to work it, the life of a car horse on those tramways is only four years. Working tramways in the north, wherever there are heavy gradients, is really cruelty to animals. We know that a horse can only do a horse's work; there are some men who can do a good deal more than an ordinary man's work, but we rarely should expect any man to do more than five or six men's work. But these tramway horses are absolutely frequently called upon to do eight or ten times more than nature has constructed them to do, and it is no wonder that their life is so very short. The remarkable fact comes out in dealing with horses from a pure matter of fact point of view. If we work a tramcar by electricity by means of batteries placed in the car, taking the price of horseflesh and the price of batteries per ton, the cost is exactly the same—it requires a ton and a half of horseflesh, it requires a ton and a half of batteries, to work a car. The life, as I stated, of a car horse is four years, the life of a battery is four years. A horse will hardly do more than thirty miles a day; a battery will carry a car for sixty miles a day, and, in fact, when we remember

that for the price of two horses, for the life of two horses, we can work tramcars by means of electricity, then when you think that it takes 12 horses, the mere question of £. s. d. will carry the day. There is not the slightest doubt that, when the matter is properly and thoroughly worked out in a practical manner, batteries can and will work tramways, and the day is not far distant when all our tramways in and about London will be worked by means of batteries, and the poor horses relegated to duties for which they are better fitted.

We will now go back to some of the other purposes, and the one purpose that I wish to refer to is the power that electricity gives us to utilize the waste powers of nature. Wind, tides, and falling water are to be found everywhere, and if they can be utilised economically will certainly be so used. I have shown you, in the case of the Portrush Railway, how water power is utilised in this way. In the Bessbrook and Newry Railway, water power is utilised in precisely the same way. At Cragside, near Newcastle-on-Tyne, Lord Armstrong is able, by means of the energy of a waterfall in his grounds, to light up his house and to do various other things. In France M. Felix has used this same property for ploughing. You will see on the screen a picture of the way in which the power of electricity is so used.

There is another application of electricity that has been attracting a good deal of attention at Brighton. Mr. Volk, who has done a great deal towards the application of electricity down there (he has laid an electric railway along the beach), has started an electric dog-cart. He has fitted a dog cart with batteries, and it goes bowling about Brighton without a horse. He, his wife, and daughter, are to be seen taking their airing along the Parade in a vehicle that looks like a dog-cart, but there is no horse in it.

Electricity is also used for propelling boats, and you see a picture of the "Cygnus," a boat used at the Paris Electrical Exhibition of 1881; a little Trouve motor works the screw. Now you see a picture of the boat "Electricity," and the rate at which these boats are propelled is pretty considerable. There is a diagram on the table of the electric launch recently tried at Havre by the French navy; it is not a very elegant-looking boat, but I believe it goes with great velocity, and gives satisfaction. I have had the pleasure of going up the Thames in an electric boat made for the Duke of Bedford, and I have been up the Danube in another electric boat. I am looking forward to the time when we may have electric boats on the Thames. It only wants some enterprising firm to establish machinery at charging depôts at Teddington, Reading, and other places, to enable boats to be propelled by electricity.

All the applications of electricity that I have shown you have been by way of peaceful purposes, but the same power can also be used for the destruction of our enemies. I have here a miniature ship in a bath containing water. It represents a pirate vessel with its black flag and skull-and-cross bone ensign flying, sailing along seeking its prey. On the pan containing the water there are two marks, and when the boat gets between them I know it is in the vicinity of a submerged torpedo, and on sending an electric current the torpedo explodes and blows up the ship and all its crew to destruction. That concludes the experiments that I intend to show you.

I have shown you various ways in which it is possible, by the proper utilisation of electricity, to economise labour; but there is always this fear, that if too many means of economising labour are introduced it may lead to ill-health and evil. Still, when labour is saved in one direction it is given in another direction, and the result must evidently be beneficial in the long run.

I have brought before you some effects of one of the great powers of Nature, and I have shown you in these two lectures, in a very rough and hasty manner, how it is applied to useful purposes. Every single purpose which I have shown you was in itself deserving of a lecture occupying a whole evening, but, however, to the best of my ability I have endeavoured to bring these matters before you, and I have been assisted in them by the very generous way in which others have come to my help. My friend Mr. Lant Carpenter has helped me considerably: Mr. Probert, Mr. Heather, Mr. Davenport, and others have all assisted, as have Messrs. Immisch and Binswanger with apparatus.

THE ELECTRICAL ENGINEER.

Published every Friday.

Price Threepence ; Post Free, Threepence Halfpenny.

Editorial and Publishing Offices :

139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. Special Terms for a series can be arranged on application.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at THREE WORDS for ONE PENNY, with a MINIMUM charge of SIXPENCE.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations ; or it can, if preferred, be supplied direct from the Office, on the following terms :—

	3 months.	6 months.	12 months.
United Kingdom	3s. 3d.	6s. 6d.	12s. 0d.
Within the Postal Union	4s. 4d.	8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 we gave a Portrait of E. GRAVES, Esq., President of the Society of Telegraph Engineers, and stated our intention of giving a series of Portraits of eminent Electricians of the century. In fulfilment of our promise we have already issued a Portrait of W. H. WOLLASTON, M.D., F.R.S., who was in his scientific prime at the beginning of the century. This will be followed by SIR HUMPHREY DAVY, F.R.S., whose fame as an electrician is still more prominent than that of WOLLASTON. Portraits of Past Presidents of the Society are in preparation, and we hope soon to have ready that of PROF. D. E. HUGHES, F.R.S.

HOUSE TO HOUSE.

We have long held the idea that company-mongering was a curse to electric lighting ; and, holding these opinions, it will not be a matter for surprise that we feel it a duty which we owe to the public to protest against contributing towards the share capital of a company registered under the euphonious title of The House-to-House Electric Supply Company. There are companies and companies. Some are legitimately promoted, and fill a useful sphere of operation, others are merely pot-boilers to company promoters. It is unfortunate that in writing of this company we must necessarily criticise, somewhat sharply, Mr. Hammond, who seems to be the moving spirit. Mr. Hammond is not unknown to electric light fame, but history as yet fails to record any achievement of this gentleman which can be said to have contributed to the prosperity of the industry. According to the advertised prospectus Mr. Hammond is to get £5,000 cash, £5,000 ordinary shares, and the whole of the 100 founder's shares. For what is this money and these shares to be given ? The answer is : the receiver " is to give his services as managing director without remuneration for two years," and to " bind himself for five years not to become associated with any other undertaking for the supply of the electric light unless by consent of this company." Now with all due deference to Mr. Hammond, we deliberately say there is no man living, or that ever has lived, who is worth £5,250 a year as managing director to a company of this sort. The company is bound to fail before it commences operations, and might as well hang a millstone round its neck before taking a leap into the sea as to agree to such terms as these. The prospectus of this House-to-House Supply Company is trading upon the so-called success of the Brighton Company, and we read " One of the founders of this company having some time since established the Brighton Electric Light Company, which, although upon a small scale, has proved very successful, and its business is rapidly increasing," which makes us ask if intending subscribers have made themselves acquainted with the whole history of the Brighton Company. We will not enter into that history, though it is very instructive, further than to ask what has been the total capital spent at Brighton from the earliest day, not the capital of the present company, but the whole ; and to say that the existing company, in our estimation, owes whatever success it may have obtained to the ability of the Brighton manager—Mr. Wright—and to no one else. We are not inclined to go into ecstasies over this success. We have some recollection of feeling dissatisfaction with the make up of the previous balance sheet, but if the shareholders were satisfied, too low a rate of depreciation was nothing to us. The report of

the Brighton Company, as given in our last issue, is to our obtuse understanding not so very flowery. Its value very largely depends upon that "ample sum for depreciation" of the amplitude of which we are unable to judge, as neither the amount nor the rate per cent. is forthcoming.

The public is asked to find a first instalment of £175,000 in 35,000 shares, because, in reply to circulars, people have asked for some 14,000 lights. Such statements as this are to the initiated valueless; to the uninitiated they may prove a delusion and a snare. How are these 14,000 lights distributed? Are they all in one district, and even then over what area, or are they in several districts, or scattered throughout greater London? The answer to such questions would at once give a clue to the commercial value of these requests for light.

There is still one return unmentioned, which Mr. Hammond is to make for the money and shares to be handed over to him, viz., "To secure for the company, on the most favoured terms, a license to use a meter for measuring alternating currents, which has already been in practical use, and has given highly satisfactory results." Are we to believe that any patentee or manufacturer in his sober senses is going to favour Mr. Hammond over any other individual presiding over a large company? Is there only one meter in the market, and is Mr. Hammond going to get the sole right over the best meter? If not, what is the value of this promise either in cash or shares?

It will be said that we are writing against the electric light. We are doing no such thing. We are doing what every technical and commercial paper ought to do, attempting to save the public from losing its money. At the end of the lighting boom in 1882, companies had been floated with a total capital of over £20,900,000, nearly twenty-one millions of pounds, and if the public was not swindled out of the greater part of the cash collected under cover of these companies, we should like to know how to designate the result of the company mongering. We are ready by word and by deed to assist to the utmost of our ability companies which seem to have promise; but here is one that has neither promise, patents, nor works. The public is asked to shut its eyes and give. We contend that if it does give it will be in the sure and certain hope of realising a heavy loss.

If householders and others are so anxious to get 14,000 lamps installed into their factories and houses, there are a score of firms in existence at this moment able to do the work better and cheaper than any limited liability company floated on the lines of this prospectus.

In conclusion, while we have the highest opinion of the correctness of the legal statement as to the powers to run overhead wires without infringing the

Act of 1882, we do not forget that as soon as electric light wires and telephone and telegraph wires become a little mixed overhead, and a snow or wind storm brings about a general breakdown and an indiscriminate series of contacts, then, Act or no Act, powers vested in local authorities or no such powers, overhead wires are doomed.

The householder who grants way-leaves for leads carrying 2,000 volts over his house does so through ignorance, and so soon as he is made fully aware of the danger through leakage or accidental contact, he will withdraw his permission. The danger with a multitude of telephone or telegraph wires is small in comparison to the danger of a mixture of these wires with electric light wires. The immunity of Brighton to accident will no doubt be put forward; but what are the fifteen miles there compared with the length required in any general lighting in London?

ELECTRIC LIGHTING IN THE CITY.

It is not difficult to understand the position of the members of the Commission of Sewers, but nevertheless the result of Tuesday's meeting, as reported elsewhere, is disheartening to all engaged in the electric lighting industry. We are not in a position to fully discuss the figures reported to have formed the communication of the Maxim-Weston Company, because the information is as yet very meagre. Our opinion, based upon the facts of the case so far as we know them, is that the Maxim-Weston Company has put in figures at which it is absolutely impossible to do the work satisfactorily, and that this action has consigned a well-considered, well-matured scheme to possible failure. It cannot for one moment be considered by those who know anything about electric lighting, that the Brush Company's terms are high; but on the contrary, surprise has been expressed that they were so moderate.

Returning to the Maxim-Weston proposal to put up 800 lamps to light the whole City, in place of the 3,000 gas lamps at present existing, the former to give 300,000 c.p. in place of the 60,000 c.p. of gas. The initial cost of these 800 lamps, and we suppose this includes generating station, wiring, dynamos and engines, is to be less than £15,000, and the maintenance of each lamp less than £5 per annum. We will believe it when we see it, but not before. The proposed lamps, no doubt, are wonderful things, but they burn carbons, and carbons cost money, more money than will permit this estimate being taken as correct. There *must* be some mistake somewhere, and before dealing further with this matter we await enlightenment.

Book Received.—"Turning Lathes: A Manual for Technical Schools and Apprentices," with 194 illustrations. Edited by James Lukin, B.A. London: E. and F. N. Spon.

DRAKE AND GORHAM'S EXCESS INDICATOR.

It has long been acknowledged that nothing tends more to lower the efficiency and diminish the life of an accumulator than the strained action attending rapid charge or discharge. The liability of exceeding the normal rate might be obviated by the use of an automatic cut-out, but in most installations the sudden extinction of the light would be

cells in such a manner that when the two studs make contact the current from one cell only will pass through the coil of the bell. The distance between the two contacts is adjustable. The tendency of the current in passing round the loop is to cause the parts carrying the contact stud to bend upward, and should the pre-arranged limit be exceeded, alarm is immediately given by the bell, which may be fixed at a distance if required. The alarm is

Drake and Gorham's Excess Indicator.

quite inadmissible. The apparatus illustrated has been found to meet the requirements of a reliable excess indicator. It is so arranged that whenever the current exceeds the proper limit an electric bell comes into circuit, and continues ringing until the normal conditions of working are restored. The principle adopted is that of the thermic alarms, which depend for their action upon the bending of a compound metallic plate under variations of temperature. In this case a strip or plate consisting of two metals rolled or soldered together, has a

found to be practically constant and reliable, variations in the temperatures of the atmosphere being inappreciable in effect.

THE BENTLEY-KNIGHT ELECTRIC RAILWAY SYSTEM.

We illustrate on this page the standard Bentley-Knight motor truck as it appears before the car body is mounted.

The Standard Bentley-Knight Motor Truck.

narrow slit cut across its centre, thus forming a narrow flat U piece, the ends of which are rigidly held and connected to terminals, which are placed in the main circuit. The closed end of the loop is free to move, and carries a carbon stud. Immediately opposed to this is a similar stud, to be connected through an ordinary electric bell to one of the

It is entirely independent of the car body, and can be put under any existing car without cutting or alterations, and without lifting the car above its normal height. The motor is controlled from either end of the car, the only connection necessary being a chain attached to the ordinary brake spindle. By this arrangement the whole control of

the car is from the ordinary handle. Turned in one direction it throws off the brake and starts the car, while, turned in the opposite direction, it applies the brake and stops the car. The weight of the motor is concentrated on the driven axle, so that the tractive adhesion is ample at all times. The motor has a spring support, so that wear on working parts and on the track is very light, while it also permits a yielding impact of the motor on the load at starting.

Tooth gearing is used throughout, and all journals are held in rigid casings. The gearing is guaranteed to be noiseless, efficient, reliable, and durable. The brakes are hung from the truck, not from the car body, and there is, therefore, no jarring felt by the passengers when brakes are applied. The motor has been designed especially by the Thomson-Houston Electric Company. The commutator brushes are fixed in position, and need no adjustment, either for change in load or direction of rotation. The motor, therefore, requires but slight attention, and can be put under the car with perfect safety. There is no flashing or sparking under the heaviest load. But one set of commutator brushes are used, and they are adapted for either direction of rotation.

There is no heating of the motor, as it has but one layer of wire on the armature, and but a small amount of coarse wire on the field magnet. The armature is encased in oiled silk, and is moisture-proof. All journal boxes are self-oiling and dust-tight, and the gearing is encased in a dust tight boxing.

The truck shown is one of those built for the North and East River Railway, of New York City, the trucks for which are now laid through Fulton Street. It is hoped that the legal obstructions which have prevented the laying of conduit will be shortly removed, and that this road will be in full operation in the early spring. The Thomson-Houston motor, mounted on the truck as shown in the illustration, will give from 15 to 25 h.p. economically. The very heavy curves, grades, and traffic of Fulton-street necessitated ample provision of power.—*Electrical World*.

ON THE POSITION AND PROSPECTS OF ELECTRICITY AS APPLIED TO ENGINEERING.*

(Continued from page 181.)

II. ELECTRIC LOCOMOTION.

The practical methods of accomplishing electric locomotion seem to the author to be the four following:—

Firstly, the use of a third insulated rail or conductor to convey the current from the generator to the motor carried on the locomotive, contact being made by a wheel or a sliding spring or brush; while the two ordinary rails serve as a return circuit, the current being conducted from the motor to the rails through the frame, axle, and wheels of the locomotive.

Secondly, the employment of an overhead conductor supported on poles or from the roof of an arch or tunnel, contact being made either by a carrier on wheels running along the conductor, or by rubbing. The return circuit may be either through a second overhead conductor, or through the ordinary rails as in the third-rail plan.

Thirdly, the use of an underground insulated conductor, placed in a conduit between the rails, and conducting the current from the generator through a contact carriage to the motor, whence it is conveyed back through the frame, axle, wheels, and rails.

Fourthly, the employment of storage batteries, placed preferably under the seats of the car, with the motor and gear underneath, or the whole placed on a separate locomotive.

The plan of using the ordinary rails as positive and negative conductors, and insulating the wheels or axles of the cars, is attended with the objection that, owing to the rail supports having to carry heavy loads, there is difficulty in insulating the rails sufficiently to prevent excessive leakage to earth.

* A paper read before the Institution of Mechanical Engineers, February 2, 1888.

Of these four methods the first two are the cheapest and most efficient, but are applicable only to railroads; while the two other plans, of an underground insulated conductor, and of storage cells on the cars, are both applicable to street tramways.

Gearing.—Owing to the high speed at which electric motors require to run and the limited space available for them to occupy, the mode of gearing the motor to the axle of the locomotive or car forms an important consideration, more especially in places where the motor is placed upon the car which carries passengers, when noise and vibration would be most objectionable. The following five methods of gearing are those more generally employed:—(1) worm-wheel gearing; (2) pitch-chain gearing; (3) leather belting; (4) rope, either endless or not; (5) toothed wheels.

Worm gearing appears from Mr. Holroyd Smith's experience at Blackpool, where his electric tramway is worked with an underground conductor, to be the best for tram-cars. Although as a rule it is not efficient, yet if well designed and properly lubricated it can be rendered more efficient, and probably is fairly suitable for this purpose. Some tests made by Mr. Reckenzaun show a maximum efficiency of 87 per cent. The author thinks that a combination of toothed wheels and friction gear, such as has been introduced by Mr. Raworth for driving dynamos in electric lighting with excellent results where space is a desideratum, would make a silent working and durable form of gear: the friction gear would serve to reduce the speed from the motor to a countershaft; and from the latter the driving wheels of the car would be driven by toothed wheels. The form of gear employed of course depends greatly upon the nature of the traffic and of the rolling stock.

Third Insulated Rail.—As an example of an electric railway with a third insulated rail, that at Portrush, Ireland, is probably the most interesting, as being one of the first started in the world and also the longest. It was planned by Messrs. Siemens, and its total length is six miles. Power is generated by two 50 h.p. turbines, driving a dynamo which is capable of generating 100 amperes at 250 volts; the current is transmitted from the river Rush through a distance of 1,600 yards to the railway, the resistance of the line being 1.9 ohm. Pitch-chain gearing is used, and gives satisfaction. The working expenses amount to less than threepence per car-mile.

Another instance, also in Ireland, is the Bessbrook and Newry tramway, which is three miles long and three feet gauge, and is actuated by water power. The photographs exhibited, showing the arrangement of the cars, have been kindly lent by Dr. Edward Hopkinson, to whose designs the railway was constructed. A turbine which develops 62 h.p. drives two Edison-Hopkinson dynamos, each capable of giving out 25 h.p. at 250 volts. The third rail is of channel-section steel, supported in wooden blocks which apparently act admirably as insulators, the leakage being only $\frac{1}{2}$ ampere per mile, or 0.3 h.p. in all. A train consists generally of one passenger car, constructed to carry thirty-eight persons, and three goods wagons, each carrying two tons freight. The maximum speed that can be attained is 15 miles per hour. Here, also, chain gearing is employed. The cost per train-mile is 3.3d. during the busy months, and 4.2d. in slack months; these figures, however, do not include anything for depreciation on the cost of construction of the railway, which was £2,500, nor for general supervision.

Overhead Conductors.—The electric railway at Moedling, near Vienna, is a good example of the employment of overhead conductors. The number of passengers carried during the year 1886 was 342,257, according to Mr. Reckenzaun, and the average cost 3.42 pence per car-mile; the coal consumption per car-mile was 13.4 lbs. of very inferior brown coal. The current is generated by six Siemens dynamos, driven by three portable engines of 12 nominal h.p. each; the use of these engines may account for the somewhat high consumption of coal. The overhead conductors, which are carried on posts 18 ft. high and 90 ft. apart, consist of slotted tubes in lengths of 15 ft. each, soldered together; a contact carriage slides within the tube, which is 1 in. diameter inside. Spur gearing is used, but apparently is not satisfactory; the objections to it are the rapid wearing out of the high-speed pinions, the great weight of the gear, and the noise and vibration caused.

The Frankfort Offenbach electric railway, which was opened for traffic on 10th April, 1884, is similar to that at Moedling, the current being brought to the moving cars by means of slotted iron-tube conductors carried overhead. The length of the line is about $4\frac{1}{2}$ miles; the gauge is 1 metre (3ft. 3 $\frac{1}{2}$ in.). The sharpest curve has a radius of 98 $\frac{1}{2}$ ft.; the steepest incline is 1 in 30, and only 18 per cent. of the line is level. The average speed of the cars is 7 $\frac{1}{2}$ miles per hour. Two cars coupled together start from each end of the line every twenty minutes. Each car has seats for eighteen passengers, and standing-room for twelve more, the gross weight being 4 tons. The motor is placed under the floor of the car, and the connection to the wheels is made by toothed gearing. The generating station is at Ober-rad (about the middle of the line), and contains one twin engine of 240 i.h.p. and one spare engine of 80 to 100 i.h.p. In regular work one cylinder only of the twin engine is used, giving off 120 i.h.p. The current is generated by three Siemens dynamos, called 300 light; a fourth similar dynamo is in reserve. The working electromotive force is 350 volts. The current generated by the three dynamos is sufficient to keep eight cars running simultaneously.

This plan has been most largely adopted in America, where there are probably not far short of one hundred electric railways at work and projected. It has certainly the recommendation of cheapness, for a higher voltage is permissible, and consequently a smaller conductor with less loss of power than in the case of the third rail; this is more especially important for long lines. As an instance of what is being done, a railway of eleven miles in length is now in course of construction at Richmond, and forty cars are building to be worked upon it on the overhead system. Another instance is the railway at Scranton, Pennsylvania, which has been in successful operation about a year. It is four miles and a half long; five cars carrying motors from 15 to 20 h.p. are in use, and four cars with 25 h.p. motors are being constructed, each of which will be able to draw two others; the cars carry 75 passengers each. The current is generated by two 100 h.p. dynamos driven by two 180 h.p. engines, one set being spare: the potential adopted is 600 volts. The overhead conductors are of copper $\frac{1}{8}$ th inch diameter; the supporting poles are 100 feet apart, about 20 feet high, and about six inches diameter at the thick end, the return circuit is through the ordinary rails. The plant is also used for lighting the town. The potential generally employed in America for the longer lines is from 500 to 600 volts, the latter is probably the limit to which it is safe to work. With this potential two $\frac{1}{8}$ th inch copper conductors would serve to work twenty-five cars in parallel, the current per car averaging about 10 amperes. With a voltage as high as this the leakage on the third-rail system would be excessive.

Underground Conductor.—Perhaps the most important example of this plan is Mr. Holroyd Smith's electric tramway at Blackpool, which has been in successful operation for some two years. The underground conduit is somewhat similar to that of a cable tramway such as is working at the present time in Edinburgh and on Highgate hill, London; but instead of the carrier being used to grip a running cable, it is made to rub along a stationary conductor. The cost of working is stated to be less than fourpence per car mile; during one week in the season of 1886 there were 44,306 passengers carried at a cost of £45 for wages and fuel, which is less than one farthing per passenger.

Where an underground conductor is employed, the advantages of having no slit communicating with the surface of the street are so obvious that an ingenious plan has been proposed by Mr. Frank Wynne for placing the conductor in a hermetically sealed conduit under the line. A small carrier which acts as a contact-maker between the conductors and short sections of rails laid in the road, travels along the conduit, being actuated by a tiny electromotor and by part of the same current which works the tramcar above it. An absolute synchronism between the tramcar and the carrier is obtained by a simple device. The short sections of rails are in circuit only whilst the car is over them.

A plan has been proposed by Profs. Ayrton and Perry for making contact between the underground conductor

and the section of rail underneath the car, by means of the weight of the car, which actuates an arrangement of levers that make the contact so long as the car is on that section. A plan has also been proposed by them for employing the attraction of a magnet fixed on the car and keepers fixed in boxes underneath the street. The contacts on the keepers are permanently connected with the underground conductor, and when lifted by the attraction of the magnet on the car they make connection with a section of rail, putting the motor in circuit.

Storage Batteries.—Storage batteries on the car have not as yet been much used, though many experiments have been made from time to time. The problem was first attempted by Mr. Reckenzaun, who has done much to perfect the plan. The difficulty is that, if the accumulators are made light, their depreciation is high; while if they are constructed with a thoroughly serviceable make of cell, their weight is very great. The first cost of the cells is also somewhat prohibited, and their depreciation is high. A trial of this plan on a practical scale is now being made by Mr. Eliason on the North Metropolitan Tramway in London. The storage cells are placed on a separate locomotive car. The motor turns itself round on an upright pivot, by means of a bevel wheel on the armature shaft, gearing with a circular rack fixed on the floor of the car; and the revolution of the motor is transmitted to the axle of the car through mitre gear. Trials are also being made in Brussels, in Philadelphia, and in other places; but there appear to be no very reliable data as to the cost of working. The plan has been unsuccessful in the past, owing to the use of inefficient motors and gear, which require of course an increased size of battery in proportion to their inefficiency; the imperfection of the secondary batteries employed, as pointed out, has also prohibited success. With motors, speed-reducing gear, and secondary batteries all improved, the experiments now being made bid fair to demonstrate the successful working of tramways by electricity in crowded thoroughfares.

Ordinary Rails as Conductors.—The short electric railway of Mr. Volk at Brighton on this system is interesting as being one of the earliest in use in this country. The expenses amount to twopence per car-mile, being made up as follows:—

Gas for engine	1.11 penny.
Wages	0.70 "
Oil and waste	0.07 "
Repair	0.12 "
Total per car-mile	2.00 pence

The total car-miles per annum are stated to be 47,000, and the depreciation at 10 per cent. on the £3,000 cost of construction is therefore equal to 1 $\frac{1}{2}$ penny per car-mile, thus bringing up the total cost to 3 $\frac{1}{2}$ pence per car-mile. Several similar railways are now working or contemplated in seaside towns.

Cost of Working.—From these instances it will be seen that, taking into consideration the fact that the machines here employed are not so efficient as those now being made, an electric tramway may be worked for about threepence per car mile; and as the cost of horses is from sevenpence to ninepence per car mile, the importance of electric propulsion for tramcars and short railways is very evident. At the Antwerp Exhibition in 1885, when electric locomotion was beginning to receive consideration in its commercial aspect, a series of trials extending over four months on five different kinds of tramway motors resulted in the first place being assigned to the electric car, in competition with the four following plans:—The Krauss and the Wilkinson locomotives separated from the car, the Rowan engine and car combined, and the Beaumont compressed-air car. The results of these trials are given in Table III.

Notwithstanding that the use of electricity for heavy railway traffic has been predicted, the author thinks that, so long as the electricity is generated by dynamos driven by steam engines, steam locomotives will not be discarded in favour of electricity for long distances. But for light railways and suburban lines, underground or overhead, where the use of a steam engine is a nuisance, there can be little doubt that electricity must be largely adopted in the immediate future, as the number of such railways already

constructed and in course of planning is now between one and two hundred.

TABLE III.—Trials of Traction Motors at Antwerp Exhibition, 1885.

Description of Motor	Electric	Rowan.	Willkin-son.	Krauss	Com-pressed Air.
Train miles run...total	2,359	2,617	2,473	2,458	2,359
Consumption of Fuel...total	14,786	14,498	22,000	22,726	90,420
per train-mile, lb.	6.16	5.42	8.82	9.10	39.48

Underground Haulage.—Electricity has been applied to haulage in various mines. A locomotive car, worked by a current sent through a conductor fixed along the side or the roof of an underground road, could be employed economically wherever the traffic is large and the distance considerable; but there is the objection of requiring a heavy locomotive car, in order to get sufficient tractive power for starting a train of tubs.

(To be continued.)

LITERATURE.

Bart's Universal Electrical Directory and Advertiser. The electrician's "Vade Mecum," containing a complete record of all the industries directly or indirectly connected with electricity and magnetism, and the names and addresses of manufacturers in Great Britain, America, the Continent, &c. Published by W. Dawson and Sons, 148-9, Upper Thames-street, E.C.

We have received the new edition of this well-known directory, which has been corrected to date. An alteration in this edition is that the continental section has been translated into English, so as to facilitate reference. This directory differs from any other of the kind in that it pays far more attention to the obtaining of a trustworthy Continental and American list of names of those interested in the electrical industries. Of course, the great value of a book of this kind is in its completeness and the completeness of its cross references, and great efforts seem to have been made that this edition shall be satisfactory in both these instances.

CORRESPONDENCE.

PATENTS AND EXHIBITIONS.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: Referring to the notice in your issue of last Saturday respecting the Glasgow Exhibition, and in view of the several other exhibitions to be held this year in Brussels, Vienna, Munich, Melbourne, and elsewhere, will you kindly allow us, through the medium of your space, to caution investors against the danger of exhibiting unpatented inventions, under the 39th Section of the recent Patents Amendment Act.

This section is one of the most misleading character, for while it purports to protect the invention during the exhibition, and to secure to the inventor unprejudiced rights against others, it now transpires, by recent decisions in the Law Courts, that the legal interpretation of the section is that it merely affords protection to the inventor, as against his own acts, and that he is not protected against others copying, if they choose, his invention.

According to this interpretation it is injudicious for any inventor to exhibit under the section in question, for while he no doubt acquires protection against the consequences of his own acts, he is simply exposing his invention for unscrupulous speculators, to pirate and probably deprive him of any benefits he may be entitled to in connection therewith.

The remedy is not to exhibit without first taking out provisional protection—a step which affords all the security desirable under the Patent Law. Yours, &c.,

J. K. FAHIE AND SON.

Patent Offices, 10, Leinster-street, Dublin; and 323, High Holborn, London, 20th February, 1888.

INSTITUTE OF ELECTRICAL ENGINEERS.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: Mr. Walker has spoken to good purpose in suggesting the admission of ladies to our meetings, and the proposition should be well ventilated. The most important thing to determine is the desire of the ladies themselves. Unless I am mistaken, ladies now attend Prof. Ayrton's classes—indeed, Mrs. Ayrton has been lecturing to ladies upon the subject of electricity—and, as Mr. Walker says, the near future will see a large utilisation of electrical apparatus in our houses, so that the more the gentler sex know of the subject the better. Their sewing machines will be run by means of an electric motor, their mince-meat chopped by similar aid, not to speak of lighting, which, if the ladies had their own way, would soon become general. By all means ventilate the question, and if the ladies desire admission, find some method by which their desire shall be granted. Yours, &c.,

EXON.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR, —Referring to the letter of Mr. Walker which appeared in your columns of last week, in which reference is made to the admittance of ladies to the meetings of the society, I, for my part, should think there could be no reason why ladies should not be admitted, as they are to the Society of Arts, since it would be a great boon to those who are interested in electricity. I hope the subject will be followed up, and that the suggestion will be carried out. —Yours, &c.,

ELECTRICITA.

ELECTRO-HARMONIC SOCIETY.

The first amateur concert of this society will be held at St. James's Hall Restaurant on Friday, March 2nd. We have no doubt the members will attend in large numbers, the programme as arranged being exceedingly attractive:—

PROGRAMME.

Part I.

- Part Song..... "The Chapel"..... *Kreutzer*.
The Gresham Quartette.
Song..... "The Devout Lover"..... *Maude V. White*.
Mr. T. H. Harrison.
Aria..... "O, del mio dolce Ardor"..... *Stradella*.
Mrs. A. Siemens.
Piano Solo..... "Romance in F sharp (No. 2)"..... *Schumann*.
Mr. James Swinburne.
Song..... "La Serenata"..... *Braga*.
(Violin obligato, Mr. T. E. Gatehouse.)
Miss Mary Doughty.
Song..... "Salve Dimora" (*Faust*)..... *Gounod*.
Mr. S. Jaronski.
Song..... "A Kiss and Good-bye"..... *Tito Mattci*.
Miss Spagnoletti.
Part Song..... "Chinese March"..... *Otto*.
The Gresham Quartette.

Part II.

- Part Song..... "The Young Musicians"..... *Kucken*.
The Gresham Quartette.
Song..... "Sleep, my Love, Sleep"..... *Sullivan*.
Miss Mary Doughty.
Song..... "My Friend"..... *Behrend*.
Mr. T. H. Harrison.
Violoncello Solo..... {a. Romance }..... *Goltermann*.
 {b. L'Arlequin }..... *Popper*.
Mr. W. Stepmey Rawson.
Song..... "Von Ewig Liebe"..... *Brahms*.
Mrs. A. Siemens.
Song..... "Celeste Aida" (Aida)..... *Verdi*.
Mr. S. Jaronski.
Piano Solo..... "Minuet from Fantasia Sonata, Op. 78"..... *Schubert*.
Mr. James Swinburne.
Part Song..... "When Evening's Twilight"..... *Hatton*.
The Gresham Quartette.

Incandescence Lamp "vacua."—M. Hees has made some experiments to determine the effect, from a photometric point of view, of diminishing the vacuum ordinarily obtained in incandescence lamps. He found, by gradually admitting air, that no appreciable effect occurred until the tension of the enclosed air corresponded to 2 millimetres of mercury; from this point the light, with a given current, rapidly diminished, until, when the tension was 6 millimetres, the illuminating power fell to one-third of its initial value.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

THE DISTRIBUTION OF ELECTRICITY BY MEANS OF SECONDARY GENERATORS OR TRANSFORMERS.*

BY J. KENNETH D. MACKENZIE, MEMBER.

(Concluded from page 183.)

Two points now claim our attention, as they bear directly upon the question of the dynamo. Shall this yield a current of the potential required in the supply mains? In other words, shall it be a high-potential and small-current dynamo, or shall it be one which gives out a large current at a lower potential? In the latter case it will be necessary to pass this current

FIG. 12.

FIG. 13.

through a transformer which will convert the electricity supplied into its required proportions, or, in other words, will raise the potential and diminish the current. In actual practice I do not believe that this application at present exists. I had the advantage of discussing the matter thoroughly in 1884 with Dr. Orazio Lago, of New York, when he was in this country watching the early experiments of Messrs. Gaulard and Gibbs on the Metropolitan Railway, and we made some experiments which led me to consider such an arrangement advisable in certain cases, and I have no doubt that before long it will be put into use in certain installations now in contemplation. The arrangement is shown in Fig. 16, where, however, two such main transformers are seen coupled together, so as to supply current upon a three-wire system.

FIG. 14.

I am inclined to believe that this employment of potential-raising transformers, even with their attendant loss in the transformation of the energy, offers advantages over direct working, since the cost of construction of low-potential dynamos is less than that of high ones, and greater reliability may be obtained, as well as more perfect control over the supply into the mains.

Upon this subject, however, makers of alternating-current machines may be able to enlighten us more fully, as the questions involved apply more directly to details of construction in the dynamos. These main transformers can of course be equally applied, whether the other transformers be connected in parallel or series upon the supply mains.

We will now turn our attention to the mains connected to the primaries of the transformers supplying them with current for

transformation, as well as those delivering the current from the secondaries. I usually term the former "supply mains," and those which run from the secondaries into the lamp or other receiving system "distributing mains," and as such I will hereinafter refer to them.

Figs. 12, 13, 14, and 15 show theoretically various methods of connecting transformers to the supply mains.

Fig. 12 shows one transformer in parallel arc to the supply mains supplying lamps in parallel.

Fig. 13 shows two transformers coupled together in parallel, and also in parallel with the supply mains, their secondaries being also joined in parallel to the lamp circuit.

Fig. 14 shows several transformers in parallel, their secondaries, being also united in parallel, thus forming a network system of distributing mains.

Fig. 15 shows a three-wire system of distribution, the dynamo having two circuits, and the transformers being placed in parallel across each of the two sets of supply mains. These mains would, of course, be calculated upon the same lines as if an ordinary direct supply three-wire system were being erected. I do not know whether this application exists in practice, but it would offer advantages in many ways in a large undertaking.

FIG. 15.

Since the supply mains have to carry currents of very high potential, it is advisable that their insulation from one another, and from earth, be as high as possible, and consequently, where feasible, it is better to put them above ground. Such, however, is not always possible, as local authorities in some places, notably in Paris, will not permit this, and the question of proper insulation then becomes a serious matter. Another question also involved, and one which makes an important feature to be considered, is the tendency that alternating currents have to break down the dielectric of their conductors, especially when such conductors are in close proximity to the earth, and retardation of the current under these conditions also comes into the question to an extent not occurring with aerial lines. I know of but one supply station working on this system with high-potential transformers in parallel where the supply mains are placed under ground, and this is at Tours, in France. M. Naze, the engineer who

FIG. 16.

carried out the work, however, tells me that he has experienced but little difficulty from these sources, although the installation has been at work now for over two years. The mains, both supply and distributing, are laid in earthenware troughs under the pavement in the streets. Fig. 17 shows in cross section an arrangement I would propose, which resembles in many respects that adopted at Tours, and which I have reason to believe would be found efficacious. The troughs (rectangular in form) would be about 4ft. long and 15in. deep, having spigot and socket joints at the ends, after the manner of ordinary socket pipes, so that complete continuity could be maintained. Transverse pieces of wood, resting upon longitudinal projections inside and on the sides of the troughs, would serve to support the mains, both supply and distributing; and a cover, recessed along each edge of its bottom as shown, would make the conduit thus formed fairly water-tight. This cover would also have lapped ends. Any leakage that might occur into the trough would fall to the

* Paper read at the Society of Telegraph-Engineers and Electricians, February 9th, 1888.

bottom, and an arrangement for drain-off holes would be provided, so as to keep the conduit clear from accumulated water. The transverse wood joints in themselves offer a fair amount of insulation, and if paraffined would be but little hygroscopic. The mains would be led away, where required, into the houses through stuffing glands in the sides of the troughs. Repairs and alterations to connections could easily be effected in a conduit of this description. The question involved is, in my opinion, of considerable importance, as sooner or later conductors for lighting purposes will have to go underground in most of our European cities.

Where the supply mains are erected overhead, they may be either supported on poles fixed to the roofs of buildings, as has been done in the supply system from the Grosvenor Gallery, or they may be carried on poles which are placed along the roadways or streets, as is usually the case in the United States.

FIG. 17.

Fig. 18 shows the top of the poles that are used by the Westinghouse Electric Light Company, of Pittsburgh, and employed in most of their installations. It will be observed that the transformer itself is supported and carried by the pole in an arrangement devised by Mr. Stanley, of that company, which is very complete and effective.

Generally speaking, where the supply mains are somewhat heavy, it is, in my opinion, advisable to suspend them on bearers, having a factor of safety of at least ten times that of the strain to which they would normally be subjected. The mains would be suspended from these bearers by insulating rings encircling the main, and attached by wire to the bearer at regular distances

FIG. 18.

of about a yard. The bearers should themselves be of stranded copper wire in cities like this, where free sulphur is so prevalent in the air; and this has lately been done in London, the old steel bearers being replaced by the new copper wire ones. Possibly phosphor-bronze would be very suitable for purposes of this nature, as it possesses great tensile strength. Both bearers and mains should be carried on insulators, which should have the form of double shackles, as this enables branches to be taken off without disturbing the line when up, and also affords greater strength and solidity. When the Grosvenor overhead circuit was first put up for use with series transformers, Mr. Brougham and I employed cast-iron boxes on the poles, into which the ends of the supply mains were brought and sweated into insulated brass sockets, as shown in Fig. 19; but although great care was taken to close all the joints carefully, moisture to a considerable

amount collected inside, and they were ultimately abandoned. In less humid climates, however, they might prove adaptable; and if the transformer cases shown in Fig. 18 can be kept water-tight, certainly these also should be so. The arrangement of connection in these "junction boxes" explains itself.

One point of interest in connection with the use of bearers should be noted, which is that since the bearers run parallel throughout their length with the supply mains, they become inductively charged with electricity. Now, if the ends of the bearers be left open, no current can flow through them; and similarly with the case of a series-transformer with the secondary ends open, a counter electromotive force is opposed to that existent in the adjacent main, which, to a greater or less degree, is retarded thereby. Hence, it appears advisable to "close the

FIG. 19.

bearer circuit," if such a term may be employed, and to close it by means of lightning arresters to earth at each end. This is not a "metallic" closing of the circuit, but somehow it appears to produce the desired effect, and also at the same time affords a protection to the line. I am speaking here of lines of several miles in length; of course on shorter circuits the effect is not considerable.

FIG. 20.

The distance between the two supply mains should be not less than 12 in.; and as, practically speaking, they are at a given moment of opposite polarity, the effect of the current flowing through them is, upon telephonic circuits even, almost nil. Possibly some here may remember that when the Grosvenor supply station was started, almost two and a half years ago, havoc was played with the United Telephone Company's wires in that part of London, and to a greater or less degree the effect was felt throughout their whole system. We were then working transformers in series, and consequently had but one wire; and the annoyance grew to such an extent that the company commissioned Dr. Hopkinson to meet Mr. Brougham and myself and study the matter, to find a remedy, if possible, for the trouble they suffered. After several experiments, we found that it was only necessary to run a return wire, and the difficulty

would cease, which was at once done. I mention this fact, as it may be of interest now that telephone exchanges exist in almost every large town, and the proprietors might raise difficulties in the way of electric light enterprises based on the employment of alternating currents, from the fear that their systems of telephonic communication might be seriously affected and prejudiced.

One peculiar feature connected with electric lighting systems employing alternating currents I wish to bring to your notice, as it may be of interest as well as instructive. It relates to the use of lead-covered cables as conductors. In many ways these cables offer advantages as regards mechanical protection which are not possessed by others, but the mere fact of the existence of this metal covering brings into play difficulties which might not have been supposed likely to occur.

An installation has been erected in Aschersleben, in Germany, by the National Company, owners of the Gaulard-Gibbs patents, which has for a long time worked successfully. When it was first started, however, lead-covered wires were employed as supply and distributing mains, and, though great care was exercised in laying them down, it was found that no insulation could be maintained, as they were always breaking down and becoming useless. The reason was due to this interesting fact that the alternating current flowing through the cable set up an induced current in the lead covering, which at places along its length used to spark across to the supports—at first very slightly, but sooner or later to a considerable extent; the lead covering would then at these places become melted, and so exposing and injuring the dielectric completely break down the insulation. The lead-covered cables have since been discarded, and ordinary conductors employed. It must be noted, however, that under any circumstances good insulation is difficult to maintain in this installation, for Aschersleben being the site of chemical and salt

FIG. 21.

works, everything becomes more or less impregnated with that substance after a time, and so the chances of a breakdown through imperfect insulation are greatly enhanced.

In designing an extensive electric light installation in a town, one of the main points to be considered is where the transformers are to be placed. Generally speaking, two courses are open—either to place a transformer in each house, or to locate transformers at various places in the town with distributing mains from them along the streets, overhead or underground, to supply the houses as required.

In many cases the first method is preferable, where, as at the Grosvenor Gallery central station, a supply is given to but a comparatively small number of the neighbouring houses, and customers can be, as it were, selected, and where the installation is in the first instance erected as an experiment. Under these and similar conditions, transformers placed in each house to be lighted is perhaps the best method of proceeding; but in all installations based on a thoroughly practical design distributing stations must be employed as a means of obtaining a more perfect supply and control over the system. The transformers are thus placed out of the reach of all but the company's servants, and cannot be tampered with, whereby accidents are more easily avoidable. The position of these transformers depends, of course, upon the amount of lighting to be done in their neighbourhood, and I prefer to so locate them that the furthest house supplied is not more than 120 yards from the nearest transformer. This allows but little fall of potential in the distributing mains from each instrument, and, as Professor Forbes showed in his Cantor Lectures before the Society of Arts, is about the most economical distance at which lights can be worked.

The Westinghouse Electric Company, in their installations, couple all their secondaries or distributing mains together throughout the area lighted, thus equalising the potential over

the district, and also in the case of a breakdown of one transformer preventing the extinction of the lights which were fed by that particular instrument. This system is practically a "network" system of distributing mains (Fig. 14), and involves a large amount of calculation in proportioning the sizes of the conductors, especially of those which join one group with another, if an installation is to be thus carried out properly and carefully gone into. I believe in practice, however, our American friends do not trouble themselves much with regard to this matter, but continue on with the cables used in the neighbouring districts.

Transformers, when thus placed to supply districts, may be located in cellars, in little street boxes under lock and key, or may be placed on the poles as before described.

I have here a plan of the mains, supply and distributing, worked out for the town of Port of Spain, Trinidad, which installation will be an interesting one, from the extent of the area lighted. I have not adopted the network system in this instance at present, on account of the scattered position of the houses; but later on probably all the secondaries will be coupled up, when the lighting in the town becomes general.

All transformers should be protected by fuses or cut-outs, and one of these should be placed on each wire leading from the supply mains to the instrument. On account of the high potential employed, I prefer to use that kind which consists of a thin wire of a length not less than six inches, having a weight, such as a lump of plaster of Paris, in the middle, in order to break the circuit quickly when the fuse goes. It is astonishing the length of arc that can be maintained by a current of 2,400 volts when the circuit is broken, and therefore I think these fuses should be long and well weighted. The secondaries should also have fuses attached between the poles of the transformers and the distributing mains, though these may be of the ordinary type in use with low potentials.

A switch should be provided to open the circuit leading to the primary poles of the transformer, and all switches which thus control high potential circuits should be made to snap open very quickly, and be so constructed as to make it impossible that they should remain in any other position than hard on or hard off.

FIG. 22.

FIG. 23.

With regard to the wiring of houses and buildings supplied with electricity by means of transformers, the rules in force in ordinary installations are of course applicable throughout, but I would remark that on no account should existing gas fittings be utilised in any building, as the chances of a breakdown are very considerably increased. At the Grosvenor Gallery supply station this was brought forcibly to my notice on more than one occasion, and I may mention one instance which occurred some two years ago which will show you what risk is run when gas fittings are so employed.

In a large shop in New Bond-street some of the gas fittings were utilised by the contractor for the attachment of glow lamps, and all went well till one evening a short-circuit occurred on one of the gasoliers, and the shop was left in darkness. They at once sent over to the Gallery to know what to do; and shortly after a servant came round from a consumer's house in Bruton-street to say that all the lights were out, and in a few moments other messengers came, informing us of further failures of the light elsewhere on the supply circuit.

We found that the current had gone to earth at the shop in Bond-street, destroying the insulation between the primary and secondary of the transformer, and thus putting the primary current to earth. A weak spot existing in the lamp wires at the other house immediately developed itself in the same manner, again breaking down the insulation and putting the primary current to earth at that place as well. The result was that all those consumers situated between the two breakdowns were left in darkness, as the current traversed the earth, or rather the gas pipes, between the two places where the breakdowns occurred, instead of going through the line. When the two faulty transformers had been switched out of circuit, the current again flowed through the line and the intervening transformers, thus restoring the supply.

I would remark that at that time the transformers were in series, but I can quite conceive a similar state of affairs occurring on a parallel supply system.

There appears no real necessity ever to use gas fittings; but if it be a question of expense, let them be entirely disconnected from the gas pipes, and then of course they may be used as any ordinary electric light fittings.

Every house, when supplied from distributing mains, should have a main switch to control the supply within the building, and where meters are employed this should be placed between the meter and the main. Preferably these should be "double-pole" switches. Fumble cut-outs ought also to be employed in the house mains, and these should be proportioned to suit the maximum current supplied to the house.

In the States, the Westinghouse Electric Company employ almost invariably glow lamps of 50 volts, as they find that these last longer and are stronger than the ordinary 100 volt lamps.

I have now tried to lay before you and explain the general principles of electrical distribution by means of transformers, without entering into theory or into other scientific and theoretical details which the subject involves, since such matter requires independent discussion. My object has been to give you a general outline of the principles involved, and their practical application, as well as some of the experiences I have gained in the matter since I first took it up with Messrs. Gaulard and Gibbs in 1883.

Before concluding, however, I would like to draw your attention to the results of some experiments made by Mr. William Stanley, jun., of the Westinghouse Electric Company, and which were briefly described in the American journal the *Electrical Engineer* of September, 1887. I have had no experience myself of what he describes, and can only refer to him as my authority.

Figs. 20 and 21 will show the theory of his apparatus, which, by the way, he calls an "auto-converter," as it consists of but one coil only, and no distinct primary and secondary circuits.

Fig. 21 shows one method of raising the potential by means of this "auto-converter." A B is a converter consisting of a single coil, and as it is evident that one half of the coil acts to the other half as the primary of an induction coil to its secondary, the potential between A B is constant, and double that of A C. A current of, say, 500 volts could be applied between the points A C of the coil, and if A C were to equal C B, a current having a potential double that of A C could be taken off between A B—in this case 1,000 volts.

Fig. 20 shows theoretically an auto-converter reducing the potential. A B is a coil of one circuit only, and is divided into four equal divisions, viz., A E, E D, D C, and C B. If the potential between A and B be 400 volts, since the subdivisions are equal, they will each have a fourth part of the initial potential, and therefore may be employed individually to supply similar receivers as shown. If the resistance between adjacent divisions be equal, the arrangement becomes a series multiple coupling, and the coil A B has no work to do, consequently losing nothing by conversion. If, however, the resistance between any two adjacent divisions is varied—say, for instance, increased—then that portion of the coil A B included between these divisions acts as a primary to the rest of the coil, and the potential difference between all the branches remains constant.

From this it appears that the coil acts only to supply an induced current to such resistances in any division as are less than the resistance of the neighbouring branches, and therefore the loss due to conversion is simply that due to the conversion of the current flowing through the algebraic sum of the resistances of the separate branches or divisions. This form of converter possesses the same merit in potential distribution that the three wire system does in the direct system.

I am not aware whether these auto-converters have been used in practice, and I feel considerable doubt as to what the result might be. One difficulty which appears likely to stand in the way of success with such a system of conversion is that as the high potential mains are directly connected to the lamp or other receiver circuits, not only are such receivers placed at an equal potential above the earth with the main, but any failure or breakdown in the insulation of the receiver circuits would result in a tendency to destroy the whole insulation of the system, not only at the particular instrument directly connected to the fault, but along the whole line. When breakdowns occur in the insulation between the secondary of an ordinary two-circuit transformer and the earth, there is, at any rate, the insulation between the secondary and primary existing as a safeguard against putting the primary also to earth.

I will now conclude by referring you to Figs. 22 and 23, which will graphically show you what the development of electrical distribution by transformers or secondary generators has done towards lessening the cost of a general electric supply; although, instead of "lessening the cost," we should, I think, say "rendering electric supply possible." The figures are taken from Dr. F. L. Pope's article in the American journal before mentioned. In Fig. 22, A B and C are drawn double the natural size, but show proportionally the area of cross section of the total mass of copper necessary to supply 5,000 16-c.p. glow

lamps, situated at a mean distance of 4,000 feet from the dynamo. A refers to the three-wire system, working at a potential of 200 volts, with a full of potential or loss of energy in the feeders of 10 per cent. the usual conditions under which this system is worked. B shows the size of conductor required for the same work in an installation based on the transformer system, allowing 25 per cent. loss in the supply mains—only one-fourth as much as in the direct system. If this loss were increased and made equal to that in the direct system, viz., 10 per cent., the size of conductor would be that shown at C.

Fig. 23 shows what the relative cost would be between each of the three conditions just named. This speaks for itself.

I believe you will agree with me that the introduction of transformers as applied to electric distribution is the greatest step forward that has been made since the great Electrical Exhibition in Paris of 1881.

I append a list of towns in which, as far as I can ascertain up to the present moment, alternating current and transformer supply stations exist, giving the approximate number of lights supplied; but it must of necessity be incomplete, through causes which those who have also tried to collect statistics can appreciate.

CENTRAL ELECTRIC LIGHT STATIONS ON THE TRANSFORMER SYSTEM.

AMENDMENT TO ACT, 1882.

LORD THURLOW'S BILL INTRODUCED INTO THE HOUSE OF LORDS.

Act to amend the Electric Lighting Act, 1882.

Be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same as follows:—

1. Notwithstanding anything in the Electric Lighting Act, 1882, no Provisional Order authorising the supply of electricity by any undertakers within the district of any local authority shall be granted by the Board of Trade except with the consent of such local authority, unless the Board of Trade, in any case in which the consent of such local authority is refused, are of opinion that, having regard to all the circumstances of the case, such consent ought to be dispensed with.

and in such case they shall make a special report, stating the grounds upon which they have dispensed with such consent.

2. Section 27 of the Electric Lighting Act, 1882, is hereby repealed, and in lieu thereof the following provisions shall have effect; that is to say,

Where any undertakers are authorised by a provisional order or special Act to supply electricity within any area, any local authority within whose jurisdiction such area, or any part thereof, is situated, may, within six months after the expiration of a period of forty-two years, or such shorter period as is specified in that behalf in the provisional order, or in the special Act, from the date of the passing of the Act confirming such provisional order, or of such special Act; and within six months after the expiration of every subsequent period of ten years, or such shorter period as is specified in that behalf in the provisional order, or in the special Act, by notice in writing require such undertakers to sell, and thereupon such undertakers shall sell to them their undertaking, or so much of the same as is within such jurisdiction, upon terms of paying the then market value of the goodwill of the business and of all lands, buildings, works, materials, and plant of such undertakers suitable to and used by them for the purposes of their undertaking within such jurisdiction, such value to be in case of difference determined by arbitration: Provided that the value of such goodwill, lands, buildings, works, materials, and plant shall be deemed to be their fair market value at the time of the purchase, due regard being had to the nature and then condition of such buildings, works, materials, and plant, and to the state of repair thereof, and the suitability of the same to the purposes of the undertaking, and, where a part only of the undertaking is purchased, to any loss occasioned by severance, but without any addition in respect of compulsory purchase. The Board of Trade may determine any other questions which may arise in relation to such purchase, and may fix the date from which such purchase is to take effect, and from and after the date so fixed, or such other date as may be agreed upon between the parties, all goodwill, lands, buildings, works, materials, and plant so purchased as aforesaid shall vest in the local authority which has made the purchase, freed from any debts, mortgages, or similar obligations of such undertakers or attaching to the undertaking, and the powers of such undertakers in relation to the supply of electricity under this Act or such provisional order or special Act as aforesaid within such area or part thereof as aforesaid shall absolutely cease and determine, and shall vest in the local authority aforesaid.

3. Notwithstanding anything in the last preceding section contained, the Board of Trade may by any Provisional order to be made by them under that Act, if they think fit, vary the terms upon which any local authority may require the undertakers to sell, and upon which the undertakers shall be required to sell to such local authority their undertaking, or so much of the same as is within the jurisdiction of such local authority under the said section, in such manner as may have been agreed upon between such local authority and the undertakers.

4. (1.) Where in any case any electric line or other work may have been laid down or erected in, over, along, across, or under, any street, for the purpose of supplying electricity, or may have been laid down or erected in any other position for such purpose in such a manner as not to be entirely enclosed within any building or buildings, or where any electric line or work so laid down or erected may be used for such purpose otherwise than under and subject to the provisions of a licence, order, or special Act, the Board of Trade, if they think fit, may, by notice in writing under the hand of one of the secretaries or assistant secretaries of the Board of Trade, to be served upon the body or person owning or using or entitled to use such electric line or work, require that such electric line or work shall be continued and used only in accordance with such conditions and subject to such regulations for the protection of the public safety and of the electric lines and works of the Postmaster-General as the Board of Trade may by or in pursuance of such notice prescribe, and in case of non-compliance with the said regulations then the Board of Trade may require such body or person to remove such electric line or work. Provided that nothing in this sub-section shall apply to any electric line or work laid down or erected by any body or person for the supply of electricity generated upon any premises occupied by such body or person to any other part of such premises.

(2) Where in any case any electric line or work is used for the supply of electricity in such a manner as to injuriously affect any telegraphic line of the Postmaster-General, or to affect the telegraphic communication through any such line, the Postmaster-General may, by notice to be served upon the body or person owning or using or entitled to use such electric line or work, require that such supply be continued only in accordance with such conditions and regulations for the protection of the telegraphic lines of the Postmaster-General and the telegraphic communication through the same as he may by or in pursuance of such notice prescribe, and in default of compliance with such conditions and regulations the Postmaster-General may require that the supply of electricity through such electric line or work shall be forthwith discontinued; provided that nothing in this sub-section shall apply to the supply of electricity through any electric line or work laid down or erected under and subject to the provisions of any licence, order, or special Act, or which may be used in accordance with any conditions or regulations prescribed by the Board of Trade by or in pursuance of any notice given by them under this section.

(3.) If any body or person fails to comply with the requirements of any notice which may be served upon them or him under this section, such body or person shall be liable to a penalty not exceeding twenty pounds for every such offence, to be recovered summarily, and any court of summary jurisdiction, on complaint made, may make an order directing and authorising the removal of any electric line or work

specified in such notice by such person and upon such terms as they may think fit.

(4.) Any notice authorised to be served under this section upon any body or person may be served by the same being addressed to such body or person, and being left at or transmitted through the post to any office of such body or the usual or last known place of abode of such person, and any notice so served by post shall be deemed to have been served at the time when the letter containing the notice would be delivered in the usual course of post, and in proving such service it shall be sufficient to prove that the letter containing the notice was properly addressed and put into the post.

(5.) In this section terms and expressions to which by the Electric Lighting Act, 1882, meanings are assigned shall have the same respective meanings, provided that the term "street" shall include any square, court, or alley, highway, lane, road, thoroughfare, or public passage or place whatever, and the expression "telegraphic line" shall have the meaning assigned to it by the Telegraph Act, 1878.

(6.) Nothing in this section shall apply to any electric line or work of the Postmaster-General, or to any other electric line or work used or to be used solely for telegraphic or telephone purposes.

5. This Act may be cited as the Electric Lighting Act, 1888; and the Electric Lighting Act, 1882 and this Act shall be read and construed together as one Act, and may be cited together for all purposes as the Electric Lighting Act, 1882 and 1887.

ELECTRIC LIGHTING IN THE CITY.

At a meeting of the City Commission of Sewers, held on Tuesday, at which Mr. W. H. Pannell presided, the Streets Committee brought up a report submitted for adoption an amended arrangement with the Anglo-American Brush Electric Light Corporation for lighting a district of the city by means of electricity. The district to be lighted commenced from the front of the Royal Exchange, and comprised so much of the city as lies between the Poultry, Cheap, St. Paul's, Ludgate-hill, and Fleet street on the north, and Queen Victoria street and the Embankment on the south.

Mr. J. C. Bell, in moving the adoption of the report, referred to the previous connection of the Commission with experiments in electric lighting in the city. In 1878 they tried the Jablochkoff system, at an expense of 7½ times the cost of gas, but, as far as they could judge, it failed. In 1881-82 they entered into contracts with three companies for experimentally lighting the city at the same time, to test which was the better system. The Brush Company charged for works, installation, and lighting in the district allotted them, £1,410, or twice the cost of the gas there, but the light gave 15 times more illuminating power. The Lontin system cost £2,930, or four times the cost of gas, the illuminating power being 14½ times greater, and the Siemens system cost £3,720, or 3½ times the cost of the gas in the district allotted them, the illuminating power being 13½ times greater. They afterwards entered into a contract with the Edison Company for lighting a part of the city with incandescent lights. None of these systems or experiments gave satisfaction. The terms of the present proposed contract with the Anglo-American Brush Company were double the price of gas in the same area—viz., £4,394 instead of £2,200—but they would get 32 times the amount of light. It was contemplated to use 196 arc lamps of 2,000 candle-power each, at a cost of £226 per annum each. The committee had selected the most frequented parts of the City for the experiment, but if it proved a success, there would be no difficulty in extending it throughout the City. He believed the contract was not only a fair one, but virtually a one-sided one in favour of the public. They had had complaints from many quarters of the insufficiency of the lighting in the City, but any increase in the number of gas lamps would be very expensive. Electric lighting would not only afford a greatly better light, but would minimise the risk of fire and tend to the protection of property. The cost would necessitate an increase of one-eighth of a penny in the pound on the rateable value of the City, of which about one-fifth of the whole area would be lighted by electricity. To those who had any experience of the atmosphere of the large establishments of the City, where hundreds of workpeople were employed, such as the printing offices—the advantage to health by the introduction of the electric light would be patent. While it was proposed to make a contract for a term of seven years, any failure of the Company to observe its provisions would not only bring about its immediate cancellation and the forfeiture of the deposit of £1,000, but would inflict on the Company the loss of their monopoly of private lighting, so that in their own interest the Company would take care to have no failure. The whole of the installation was to be finished by October, 1889, but they hoped to have the City lighted street by street as the work progressed. The Company would have, as far as the Commission could grant it, a monopoly of private electric lighting in the district, but they could not compel the inhabitants to use it, and it was, therefore, to their interests to make the charges as low as possible in order to secure orders and to compete with the gas supply. The same monopoly of lighting was now given to one gas company, with the result that the cost of public street lighting was decreased. In the present case it was estimated that each arc lamp in the streets would cost £40 per annum to the Company, who would therefore, lose £14 on each lamp, but they would bear this loss for the sake of the monopoly of private lighting. If the experiment proved successful they might go to other companies and get better terms, and if it were a failure they could fall back upon the gas, besides making the company pay for the failure. It had been suggested that the Commission might undertake the work more economically and just as efficiently themselves, or, at all events, that they should have a right of pre-emption of the shares of the Company, but as electric lighting was still in its infancy, he thought that at this period they had better let other people who understood

the work do it. He contended that arc lighting was the proper mode of illuminating a city such as London, and observed that the contract contemplated the provision of gasless lamps, and of glow lamps in the smaller streets. He believed that if the work was carried out as proposed the Commission would be entitled to the thanks of the community. At all events they would be likely to bring the gas companies to their bearings. Even that small agitation had had the effect of reducing the price of gas by 6d per 1,000, and he hoped that sooner or later the gigantic gas monopoly would be broken down. For these reasons he urged the Commission to adopt the report.

Mr. C. T. Harris, as an amendment, moved that the report should be referred back for further consideration. He argued that the present lighting of the City, as far as all practical purposes were concerned, was perfectly sufficient, and that anything further would be merely a luxury, for which the ratepayers should not be called upon to pay an increased tax. He objected to the report on four grounds—viz., because arc lighting was unsuitable for the purpose, because the illuminating power could not be adequately estimated, and was, therefore, enormously exaggerated, because the cost was prohibitory, and because he considered the terms of the contract open to grave criticism in the interests of the public. On these grounds he begged the Court to give the matter further consideration.

Mr. J. E. Sly observed that four or five years ago a great deal of money was spent by the Commission in experiments with the electric light. It was hardly for the Commission to contemplate lighting one portion of the City at the expense of the other. They had shown their desire for the light by the large sum of money they had spent in experiments. If they contemplated adopting the electric light it ought to be for the whole City. The Maxim Weston Electric Light Company would supply the electric light to the whole City at £15,000 for the first cost fittings, &c., and £3,875 a year for maintaining the light—800 lamps of 450 candle power each being supplied. This would pay itself in two years. He asked them to reconsider the matter, so as to get it done in the cheapest way they could, and not to have a seven years' monopoly.

Mr. Bridgman referred to the insufficient manner in which the City was lighted as compared with the Holborn district, and observed that he did not know a more dismal place than the neighbourhood of St. Paul at night. The electric light had been adopted in New York, Brooklyn, Paris, Vienna, and some towns in England.

Mr. Morton said he was strongly in favour of getting the electric light, but they did not want to be entrapped.

Mr. J. V. Moore supported the amendment. He referred to the improvements which had taken place in gas lighting, and observed that gas was becoming a formidable rival to the electric light. A new lamp had been brought over from Berlin which gave a wonderful light at a consumption of only twelve feet of gas per hour. The Court could not, consistently with its duty, agree to the report, and it ought to be sent back for further consideration.

Mr. L. H. Phillips and Mr. G. Shaw also supported the amendment, while Mr. Deputy Scott warmly advocated the adoption of the report.

After some further discussion the amendment was declared to be carried on a show of hands. A division was demanded, with the result that the amendment was carried by 36 to 17. The report was accordingly referred back for reconsideration.

PROVISIONAL PATENTS, 1888.

FEBRUARY 10.

2002. A new electrical tool. Thomas Thorp, Whitefield, Lancashire.

FEBRUARY 11.

2073. An improved electric alarm apparatus. Armand C. Iwanowski, 45, Southampton-buildings, London.
2125. An improved method of constructing and regulating arc lamps. Walter Rowbotham, 39, Lever street, Manchester.

CITY NOTES.

Armstrong's Electric Company. A meeting of this Company is announced to be held at the Company's offices on the 27th inst.

Submarine Cable Company. A dividend of 15½ per cent. per annum was declared on Tuesday at the half-yearly general meeting of the Submarine Telegraph Company, the Hon. H. R. Brand presiding, at the offices, Throgmorton Avenue.

Western and Brazilian Company.—The traffic receipts of the Western and Brazilian Telegraph Company Limited, for the week ending February 17, after deducting the fifth of the gross receipts payable to the London Platino Brazilian Telegraph Company, were £23,612.

West India and Panama Company. The estimated traffic receipts of the West India and Panama Telegraph Company Limited for the half-month ended February 15, are £3,310 against £3,012 last year, showing an increase of £298, as compared with the corresponding period of last year.

Channel Cables. The *Financial News* has been giving some information about these cables, among which it says: "It is a curious fact that the British Government borrowed the idea of terminating the monopoly of the Submarine Telegraph Company from Belgium."

Mynheer Van den Peereboom, the Minister of Public Works, is well known in Belgium for his independent character. He & it pined about the 'never-minted-her policy' of Throgmorton Avenue, and he resolved to show the Submarine Telegraph people that Belgium, albeit small, is not to be trifled with. So one fine day, without telling anybody, the Minister despatched two representatives to the British capital with full powers to treat with the Post Office about the conclusion of an Anglo-Belgian telegraph convention, and the working of the two cables between Ramsgate and Ostend and Dover and La Panne, so soon as the Belgian concession to the Submarine Telegraph Company lapsed—that is to say, in January next. At that time the British Government had not even considered the matter, but Mr. Van den Peereboom's agents convinced the Post Office that by far the best plan would be to abandon the beautifully-independent Submarine Telegraph Company, put an end to its existence, and annex its property for a consolidation."

The United Telephone Company. A meeting of subscribers to the United Telephone Company was held on Monday, at 84, Bishopsgate street Within, to take into consideration the proposed change by the Company of some of the numbers held by their clients. The change affects for the most part the Leadenhall street subscribers; consequently, those who were present—some thirty in number—were, almost without exception, representatives of firms in that thoroughfare. Mr. Singer, who, by reason of the interest he has taken in the matter, was voted to the chair, commenced by detailing the steps that led up to the convening of the meeting. The company seemed adverse to the withdrawal of their notice of change, so that his firm had put themselves into communication with other subscribers, their opinions being so unanimously opposed to the change that it was ultimately decided to call the meeting to ascertain what measures should be taken to endeavour to get a redress of grievances. He had received several letters, and all, with one exception, were utterly opposed to the change. Mr. Paul failed to see what right the company had to change a number for which a subscriber had paid in advance. Mr. Fitch (Messrs. Fitch and Co.) said his firm would oppose the change on two grounds. First, that it was unnecessary; and second, that it was illegal. Mr. D. Collin (Messrs. Dunn, Collin and Co.) pointed out that if the change were carried into effect, a man in the same business as himself might be allotted his number, with the result that he would receive the orders intended for him (Mr. Collin). The Chairman said his idea was that they should apply for an injunction to restrain the company from making the proposed change. Mr. C. Haller suggested that a committee should be formed to wait upon the board of directors on the subject. Further discussion ensued, and eventually it was resolved "That this public meeting of telephone subscribers strongly object to the proposed change of numbers on the point of its great inconvenience and expense, besides leading to constant mistakes in orders and inquiries, and hereby appoints a committee to confer with the directors, and report again to the subscribers." A committee, consisting of the chairman, Mr. Fitch, Mr. Haller, Mr. Peale, and Mr. Collin, was appointed, and the proceedings then terminated with a complimentary vote to Mr. Singer.

NOTES.

Electric Lighting in Switzerland. The electric light is about to be installed in the little town of Martigny.

United Telephone Company.—The Governors of Bridewell and Bethlehem Hospitals have petitioned against this Company's Bill.

Electric Lighting Act. The Amendment Bill introduced into the House of Lords has its second reading fixed for Monday, March 5.

Eastbourne.—A tradesman has been writing to the local papers about the inferior nature of the gas supply, and says: "Why does not the Electric Lighting Company wake up and extend facilities for the more general adoption of the new illuminant? I believe scores of gas consumers are ready to transfer their allegiance."

Phoenix Fire Office Rules. The Twelfth Edition of these rules has followed very closely upon the preceding Edition, the one having been issued in December, 1887, the other in February, 1888. This shows how considerable is the demand for the rules which may be said to regulate all electric light installations in this country.

Projected Electric Lighting of Marlborough House.—His Royal Highness the Prince of Wales has recently decided to have the State apartments and principal rooms in Marlborough House lighted by electricity. The work is in the hands of the officials of the Prince's household, and the current will, it is stated, be supplied by the Grosvenor Gallery Company.

Electric Lighting in Spain. The central station at Pontevedra will shortly be completed. The installation, carried out by M. Alvar Gonzales, will comprise about 1,500 10 c.p. incandescence lamps.—The municipality of Valence, who had forbidden the use, within the town, of any boiler above from 4 to 5 h.p., have removed their interdiction in favour of the boilers made, according to the Collet system, by the *Société des Générateurs Inexplosibles*.

The Schanschiff Lamp. The Princess Christian has accepted from the Schanschiff Syndicate a reading lamp manufactured on the Schanschiff principle. It is the first of its kind that has been made adapted to domestic uses, and Mr. Schanschiff, who presented it, had the honour of explaining its working. The Princess was greatly pleased at its simplicity, and the easy manner with which the light could be regulated from one to ten candle-power or totally extinguished and immediately relighted at will in a second.

Electric Lighting Regulations. The Society of Electricians, at Vienna, recently nominated a Committee to draw up a set of regulations relative to the distribution of electrical power, which will be laid before the Austrian Parliament to serve as a basis for a new law on this subject. This Committee has just concluded its labours; and its report will be submitted to the members of the Society at their next general meeting, in order that it may be discussed and, if necessary, modified before being presented to Parliament.

The Electric Light in Italy. According to the *Bulletin des Sociétés d'Électricité*, great activity prevails at the present moment in the Italian military ports—Naples, Castellamare, Livourne, Genoa, and Spezzia. Four thousand supernumerary labourers have been engaged, and are

working day and night at the establishment of the electric light. At Cape Porto Fino, Cape Mele, and at the islands of Sardinia and Maddalena, twelve electric lighthouses are to be constructed. At the Venice arsenal also, they are working day and night in connection with electric lighting and the manufacture of torpedoes.

Long-Distance Telephoning.—A telegram dated Paris, Tuesday, says:—The French are about to accomplish another feat in long distance telephoning by the establishment of communication between Paris and Marseilles. The line will be subterranean between Paris and Nogent-sur Marne, whence it will follow the course of the Paris, Lyons, and Mediterranean Railway. The works have been almost completed in all the departments through which the wire will pass. It is only necessary now to cover some short spaces, and it is estimated that everything will be in working order by July. The first wire, which is of bronze, is rather thicker than those of the existing long-distance lines.

Brighton Electric Light Company. A meeting of the shareholders of the Brighton Electric Light Company was held at the works of the Company last week, and great satisfaction was expressed at the nature of the report for the past fifteen months. The managing director, Mr. Arthur Wright, was congratulated upon the successful manner in which he has conducted the Company's business. There had, it was stated, been a great increase in the consumption of electricity, and the plant had recently been considerably added to in order to still further cope with the business coming before the Company. It was resolved that an expenditure of £3,000 should be made on additional plant.

Cardiff Docks. We have several times referred to the lighting of the Cardiff Docks, the work of which is being carried out by Messrs. Crompton and Co. The installation has proceeded so far that a number of lamps have been put up, at an elevation of some 25ft. or 30ft., near the pier-head and the principal bridges. These, on being tried last Monday night, were found to work in an eminently satisfactory manner, so much so that electric lighting at the Cardiff Docks may now be looked upon as a permanent thing. It is expected that by the time this reaches the eyes of our readers the lamps will be in constant use, and will be considerably augmented.

Provisional Orders.—The question addressed to Sir M. Hicks-Beach last week elicited the following reply.—Since the passing of the Electric Lighting Act, 59 provisional orders and 5 licenses have been granted to companies, and 15 provisional orders and 2 licenses to local authorities. The Board of Trade are not aware of any cases in which the powers obtained are now being exercised. It is not possible to express an opinion as to the reasons which may have led to this result within the limits of a reply to a question. A Bill to amend the Act has been introduced in another place, on which the views of the Government will be stated and issues discussed.

The Electric Light in Brussels.—M. Aceto, the director of the Brussels gas works, has been appointed inspector of public lighting for the city, *vice* M. Wibaux, who has been placed in charge of the electric lighting, the electric clocks and the telephones. As our readers are aware, the installations of electric lighting in this town consist at present of the works supplying the *Théâtre de la Monnaie*, the *Grande Place*, and the *Théâtre du Parc*, but the municipal Council has pronounced in favour of a project for the construction of a central electrical station, which

would supply the light to the principal *restaurants, cafés* and public buildings. Negotiations with the *Société Industrielle* are in progress with a view to carry this installation into effect.

Barnet.—At a meeting of the Barnet Local Board on the 21st ult., Mr Marriott gave notice of motion as follows:—"That the time has now arrived for the Board to take into consideration the lighting of its district either by the electric light or otherwise, taking into account the high price of gas and the bad illumination they get for the money which they pay for the supply of gas to the public lamps." A letter was read from the Pilsen-Joel Electric Lighting Company, asking the Board to grant them permission to carry overhead wires to supply the town with electric light at a given rate, and to give them a monopoly of supply for three years. It was incidentally mentioned that the Company had canvassed the town and obtained large promises of support from intending consumers.

Telephony.—Two new telephone companies have been formed, one in Rosario, with concession for the Argentine Republic and Uruguay, the other one in Cadiz, Spain. This is a double success for Belgium, since these companies, after comparative examination of all telephonic apparatus for subscribers, have adopted the one constructed by Messrs. Moulon, of Brussels. Everyone knows that this is the very instrument used on the Belgian State telegraphic network, and which gives such wonderful results between Paris and Brussels. It is, perhaps, of all the products of the Belgian industry, the one which has the most extended market, being used not only in America, but also in China, Japan, and even in the Congo, where the network in San Thomé Island has no apparatus but those of this Belgian firm.

Electric Lighting in Belgium.—The syndicate formed by the principal electric lighting firms, with a view to the establishment of central stations for the distribution of the light, have nominated a technical committee, including the names of MM. Bonnevie, Gerard, Goffin, and Julien. This committee has already decided to submit alternative proposals of the two following kinds to the communal administrations of the towns in which it is proposed to adopt electric lighting:—1. A central station working transformers, such as those of Gaulard and Gibbs, Zipernowsky, and Goffin-Hoho. 2. A central station employing the high-potential dynamo machines of Gerard (outside the boundaries of towns) to charge accumulators such as that of M. Julien. The second system, it may be mentioned, has received a successful application in the lighting of the *théâtre de la Monnaie*, under the supervision of M. Gerard.

The Swan Company.—A report of the Swan Company's meeting will be found in another column. It is both interesting and disappointing—the former in that it promises hopes of better things—the latter in that these hopes are deferred. A substantial profit has been made on the year's working, and old losses are now paid off, so that if any profits are made in the future there is no reason why some distribution should not be made to the shareholders. The tendency of the market in the shares of the company has lately been more favourable, and if the business reasonably progresses they ought soon to reach par. The chairman arrogated a considerable amount of business talent to the directors of the company, but if they would listen to the voice of outsiders they would find that buyers are not altogether friendly to the company, and that a considerable

change of the *statute in modo* must take place during the six years of grace to enable the company to hold its *cheville*.

The National Gallery. The suggestion for lighting the National Gallery by electricity, says the *Gas Journal*, is one of those propositions which continually crop up without any real attempt being made to dispose of them. It is very true that the pictures of the National collection, as well as the invaluable contents of the British Museum, are unavailable after dark; and it is equally true, and even more provoking, that many days in London during the winter months are dark throughout. The question is, with regard to pictures, what method of artificial lighting is the best and safest? It would be of little use to art students to light up a picture gallery with either gas or the incandescent electric light, for the simple reason that either would falsify all their colours. The arc light is white enough to paint by; but would the trustees of an invaluable national collection be justified in admitting within their buildings wires carrying the strong currents required for arc lamps? It is doubtful. At all events, they do not display any eagerness to move in this direction; whereat the electricians and their friends emit periodical growls.

The Carrière Accumulator.—M. Carrière constructs a secondary battery with compressed carbon plates, having either a plane or a corrugated, grooved or recessed surface, this surface being coated with a layer, from 1 to 1.5 millimetres in thickness, of a composition made by mixing litharge with dilute sulphuric acid containing $\frac{1}{2}$ th of the strong acid. The carbon plates are manufactured by mixing 2 parts of pulverised retort carbon with one part of lamp-black or of pulverised wood charcoal, and forming these ingredients into a paste with a thin mixture of barley or wheat flour and water. This mixture, after being moulded by compression, is dried in air, again pressed, subjected for some time to a temperature of 80° C; and lastly subjected for several hours to a temperature of from 1,200 to 1,300°, when they are allowed slowly to cool. The essential features of this method of construction, we may observe, are by no means novel; and sufficient experimental evidence has we think already been obtained with similar plates to justify the conclusion that M. Carrière's anode elements will somewhat rapidly disintegrate by the effect of oxidation.

Vienna.—Herr Fischer, says *Industries*, a civil engineer of this town, has obtained a concession for an electric railway between Voslau and Rauhensdorf, near Baden, and from there to Leopoldsdorf. The length of the line being considerable, Herr Fischer will probably use storage cars; Julien accumulators are now being tested in the Electrotechnical Institute, and a trial of these cells for tramway work, in competition with Reekenzaun cells, will shortly take place. A central station for the supply of electricity has recently been erected at Neuhaus, in Bohemia. The contractor is Count Czernin, a landowner in that district, and he has arranged for the supply of light to the Commune for twenty years. Power is obtained from a turbine, and there are at present two dynamo machines installed. The distribution is on the three wire system with feeders. All the leads are carried on poles overhead. The streets are lighted by eighty-five 16 c. p. glow lamps, and in private houses there are at present 365 lamps fixed, but the demand is constantly increasing. To provide against breakdown a battery of 1,000 storage cells is now being laid down.

Paris Theatres.—The superior Commission on theatres recently held its second sitting, under the presidency of M. Leon Bourgeois, prefect of police. This sitting was almost entirely devoted to the important question of rendering unflammable the stage decorations and the woodwork in connection with them, whatever might be the method of lighting adopted. In regard to the shifting scenery, the Commission made a distinction between theatres which are still lighted wholly or in part by gas, and those in which electric lighting is solely employed. In the former, the movable scenery should be prepared with some fire-resisting composition; as regards the latter, in cases where the electric installation is approved by the technical sub-commission, the administration may, exceptionally, dispense with such process. On the motion of Capt. Krebs, the Commission decided that the wooden supports of the electric light leads, everywhere within the theatre, should be rendered fire-proof. Finally, M. Strauss brought about the passing of a resolution in which the necessity for the electric lighting of theatres was recognized in principle. The further consideration of the question was adjourned to the 23rd ult.

The Paris Exhibition.—A meeting in connection with this exhibition was held on Wednesday at the Mansion House, under the presidency of the Lord Mayor. The electrical section was well represented by Mr. E. Graves (president of the Society), and Mr. W. H. Preece, F.R.S. (past-president). The Lord Mayor said, among other things, the Government had decided not to take any official part in the exhibition, though they had undertaken to give all facilities within their power to intending exhibitors. He had received an intimation from the Foreign Office assuring him that the Government could in no way object to his assuming that position, and stating, without qualification, that Lord Salisbury would in no way regard his presidency as opposing the position which the Government had taken in the matter. The names of an exceedingly strong and influential committee were read, and it was stated that the London, Chatham and Dover Railway Company, and the South Eastern Railway Company, had promised every facility possible, and to deal with extreme liberality on all points relating to the exhibition. A number of resolutions were proposed and carried, and a guarantee fund announced to which various contributions were there and then promised.

The Telephone in Germany. The following figures show the considerable progress made in Germany during the last year in the adoption of telephonic communication:

	Oct. 1, 1887.	Oct. 1, 1886.	Oct. 1, 1885.
Number of networks	150	118	92
" " subscribers	23,968	18,245	12,897
Length of lines in kilometers..	4,311	3,705	2,597
" " wires "	39,539	31,251	23,150
Number of telephonic stations.	4,134	3,638	—

On Oct. 1 last, the number of inter-urban lines was 49, and 9 others were in course of construction. For some time past, Silesia and Westphalia have possessed a vast telephonic installation, covering the whole territory and connecting the different towns. A similar network is about to be constructed in the important industrial district of Saxe, and will include Chemnitz, Zwickau, Werdau, Krimtschaw, Plauen, Meerane and Leipzig. All the lines in this district are to be of phosphor-bronze, which appears likely to be generally employed, to the exclusion of iron,

for telephonic lines. It was used by the administration for the first time in the line between Berlin and Hamburg. Another item of news is the adoption of an underground system for these two towns.

Japan.—Thanks to the endeavours of the Belgian Minister in Japan, Mr. G. Neyt, who undertook to make known to the Japanese Government the invention of the well known Belgian electrician Van Rysselberghe, the telegraphic network of that country will soon be utilised for telephony also. All the apparatus required for an experiment has just been ordered in Belgium according to the instructions given by Admiral Enomotto Takaki, Minister of the Empire of Japan. A fact worth mentioning to those interested in the applications of electricity occurred in Japan in connection with Van Rysselberghe's invention, viz., before the Government had finally adopted the system, by desire of H. E. Inouye Masaru, Vice Minister of Public Works, a Mr. J. Fujioka, Instructor at the Engineering College at Tokio, had reported very fully on the advantages to be derived from using the system on the telegraphic lines in Japan. From simple data extracted from the books by Mr. Buels and Mr. Ch. Moulon on the system in question, he had succeeded in applying it to a telegraph line, using apparatus which he borrowed from the laboratory of the Engineering College at Tokio. He had a complete success, and was thus able to carry out an experiment which speaks highly for the enterprise and the technical knowledge of the Japanese.

The S.S. "Ocean." This is a steamer built by Messrs. Russell and Co., Greenock, for the oil trade, carrying the cargo in bulk; there are eight oil tanks, with a carrying capacity of 3,500 tons. On Friday last a large company met on board, consisting of owners and friends, builders, and several eminent engineers, to witness the trial of engines and electric light. The vessel left the James Watt dock about 10 a.m. and proceeded to run the measured mile, which was done several times to the entire satisfaction of owners and engineers, the speed being over 11½ knots; the guaranteed speed was to be 10½ knots. The electric light plant was then carefully examined and tested, and gave entire satisfaction. The plant consists of 50 20-c.p. Swan lamps distributed over the ship, and into the signal lights, masthead, and anchor lights. The binnacle also is lighted by means of the electric light. No other lights will be allowed on board, in order to ensure as far as possible safety against explosion and accidents such as have occurred on board other steamers in this trade. The dynamo employed is the Clyde Dynamo, driven by a vertical engine, and is supplied and fitted up by J. H. Carruthers and Co., under the personal superintendence of Mr. James Campbell. The speed of dynamo is 1,100 revolutions per minute, and the machine shows no signs of sparking at the brushes.

The Siesemann Ammeter. This instrument, which can be used also as a voltmeter, is based on Joule's law ($\text{Heat} = C^2 R t = \frac{E^2}{R} t = C^2 R$), and is composed of two externally similar mercurial thermometers, one of which contains in its bulb a resistance R , formed of a spiral of German silver wire, with its ends connected to the terminal screws of the apparatus. A current being passed through this wire for a given unit period, we have—calling H the heat developed—

$$C = \sqrt{\frac{H}{R}} \quad \text{and} \quad E = \sqrt{H R}.$$

The value of H may be taken as the difference of the tem-

peratures indicated by the two thermometers. In practice a moveable scale, graduated in amperes or volts, is employed, the zero on this scale being adjusted to the height of the normal thermometric column. The height of the second column then indicates directly the value of C or E in amperes or volts. For rough practical purposes at least we think this instrument likely to be useful; but we fear that the inventor is somewhat too sanguine in limiting the possible error to one per cent., since a considerable time is requisite to obtain thermic equilibrium, and during this time a loss of heat occurs by conduction and radiation. Moreover, unless the wire spiral be effectively insulated from the mercury, the value of R would not be constant, and the instrument would require frequent re-calibration. It is possible, however, that these objections may be to a great extent overcome.

Bournemouth.—A large audience assembled in the theatre at Bourne Hall on Wednesday evening to hear a lecture from Mr. W. Lynd, M.S.T.E., on the electric light. The pretty little theatre of Dr. Philpotts' well-known establishment was illuminated for the occasion by an installation specially fitted up by the Electrical Power Storage Company, besides Dr. Philpotts' private installation, which comprises an arc light of 500 c. p. and a number of incandescent lamps. The lights supplied from accumulators were suspended by flexible silk-covered wires above the stage, various coloured shades being successfully brought into requisition to soften the glare of the lamps. A very pleasing effect was produced when the light was turned on. Mr. Lynd, at the outset, spoke of the labours of Faraday, whose original experiment with the permanent magnet and the moving coil of wire he demonstrated to the audience. The next experiment was the production of the electric arc, the temperature of which, Mr. Lynd said, was almost inconceivable. Iron fuses at 1,200deg. F., platinum, the most refractory metal known, at 3,000deg. F. The temperature of the electric arc is equal to 8,500deg. F. A tolerably thick piece of wire was connected with only one storage cell, when in a second or two the covering was destroyed, and the wire rendered incandescent. The principle of the dynamo was next explained, illustrated by a machine which the lecturer worked by hand. Mr. Lynd explained some of the systems of electric lighting now in vogue, and afterwards proceeded to describe in popular language the storing of electrical energy.

Indian Telegraph Department.—In the House of Commons, Mr. King asked the Under-Secretary of State for India whether he would lay upon the table a copy of the dispatch of the Secretary of State with reference to the block in promotion and other grievances of the Telegraph Department in India; whether any officers of the department had as yet accepted the offer for retirement made in that dispatch; whether, under the system of grading instituted by that dispatch and the abolition of the privilege hitherto in favour of officiating promotions being from grade to grade, many officers were mulcted of a large percentage of their emoluments while the Government saved a very large sum, on what grounds permanent promotions were fixed by the dispatch to be made only twice a year, on April 1 and October 1, and whether he was aware of any precedent for such a provision in any other service of the Crown; whether the fixing of March 31 as the latest date for the submission of retirements had practically operated to take away the inducements for retirement in nearly all the cases, if not in every case, where retirement under the

regulations of the dispatch would have offered any advantage; and whether, in the circumstances, the Government would reconsider its proposals. Sir J. Gorst answered. (1) Yes, if the hon. Member will move for it, I will lay it on the table. (2) None. (3) No officers are damaged, as the rights of all existing officers are safeguarded. (4) No such provision is made in the dispatch. It was introduced by the Government of India, but no reasons for it have been communicated to the Secretary of State. (5) The date, March 31, was fixed to give every officer ample time for consideration. The Secretary of State is not aware that the inducement to retire has been taken away thereby. (6) The Secretary of State will wait till March 31 before further considering the matter.

Cost of the Telegraph Service. In accordance with the order of the House of Commons, a return is published showing the gross amount received and expended on account of the Telegraph Service during the year ended 31st March, 1887. From this it appears that the gross amount received for telegraphic messages, private wire rentals, special wire rentals, &c., was £2,035,124. 7s. 3d., out of which sum £189,962. 3s. 11d. was paid to the submarine telegraph companies, and £4,001. 7s. 4d. was refunded to the senders of messages. The amount of extra receipts was £14,525. 5s. 5d.; sale of old materials, £78. 15s. 5d.; sale of waste paper, £2,188; and the value of telegraph services performed for other departments, without remuneration, is set down at £29,206. 17s. 10d. The total expenditure is £2,032,632. 8s. 10½d., being £145,472. 14s. 2½d. more than the receipts. The expenditure is made up as follows:—Salaries, rent, maintenance of telegraphs, &c., £1,939,764. 3s. 4½d.; amount expended by Office of Works, London, from the grant for Revenue Department Buildings in respect of telegraph service, £51,278. 3s. 3d.; stationery, £35,259; buildings in Ireland, £2,699. 0s. 11d.; stamps used on telegrams, £334; cost of auditing accounts, £2,193. 9s. 7d.; and rates and contributions in lieu of rates, £1,104. 12s. 9d. Appended to the accounts is a statement of the amount expended on account of the annual charge for the securities created for the purpose of the Telegraph Act. The capital stock is set down at £10,880,571. 5s. 2d., the year's interest being £326,417. 2s. 9d. Adding the excess of expenditure over receipts as given above, the total deficiency of telegraph revenue to meet expenditure and the interest on telegraph stock created in the year ended March 31 last is £471,889. 16s. 11d. The deficiency in the year ended December 31, 1872, was £118,966. 1s. 1d., and this has now grown to £3,024,899. 10s. 5d.

Berlin.—The first central station, says *Industries*, in which accumulators are used has been recently started in Berlin, at No. 37, Neue Friedrichstrasse. The plant consists of two 45 h.-p. Babcock and Wilcox boilers (manufactured by Messrs. Schmidt, of Küstrin), two steam engines of 35 h. p. each, and two 18 kilo.-watt dynamos. The current is not supplied direct from the dynamo, but from a battery of flat tray pattern Khotinsky accumulators, each cell having 600 ampere-hours' capacity. The principal customer at present is a restaurant situated under the elevated railway, and a total of 500 hundred lamps is now installed; but applications for the light from neighbouring places have been received, and to provide for the extension the battery boxes have been made deep enough to admit additional plates, by which the capacity can be increased by another 600 ampero-hours. The lamps used are 150-volt Seol

lamps, and the total cost of the central station and mains was £3,500, that is, at the rate of £7 per lamp fixed. A few weeks ago I gave particulars of the electric light installation in what is known as the German theatre of this town. I am now enabled, by the courtesy of the engineer in charge, to give you details of the installation and working expenses. When gas was used in this theatre, the cost for lighting varied from £4 per day in summer, to £5. 10s. in winter; but now, with the electric light, the working expenses do not materially vary with the season, as the items of attendance and interest on the plant are a constant. The total cost of the installation was about £3,000, and this contains the following items: Engine house and chimney, £500; boiler and engines, £940; dynamos, wiring, and accessories, £905; electric light fittings, £250; and regulator for the stage, £150. The consumption of coal in winter is about 16cwt. daily, costing 18s.; attendance, 8s.; lubricant, 3s.; and interest on the capital outlay 20s., reckoning this at 10 per cent. for 300 working days. The installation has been in use too short a time to estimate accurately the cost of renewal of lamps, but this could hardly exceed 10s. a night, so that the total expense for the electric light may be taken as £3 per night, which is considerably below the sum previously paid for gas.—At a meeting of the Town Council, held on the 16th ult., it was resolved that the wiring of private houses may be left to open competition, but that the work in connection with bringing the current into the house and the installation of the motor must be undertaken by the Berlin Electric Company.

Bradford.—Dr. Hopkinson has reported upon the system of electric lighting he would recommend for the proposed installation, and, as it has been approved of, tenders will shortly be invited to complete the installation. Dr. Hopkinson's report shows that he is in favour of having the central station at Bolton-road. The report prefers the direct system, it having the advantage that a continuous current is used, available at pleasure, for charging accumulators or for transmission of power. Dr. Hopkinson recommends the three-wire system. The advantage of this system is that it saves about 12 per cent. of the electrical power, a proportionate saving in the cost of engines and dynamos, and a considerable saving in the cost of conductors. Referring to the dynamos, Dr. Hopkinson says he would incline to use five, but, at the same time, he adds a smaller number of larger machines would be perfectly successful, and would possess certain advantages over the larger number of smaller machines. The contractor should guarantee a commercial efficiency of 90 per cent. for the dynamo, and the wires should be laid in brick trenches. On the method of charging for payment Dr. Hopkinson says:—"It is very much more costly to store electricity than to store gas, consequently you must provide a plant competent to meet the maximum demand. A consumer, then, who takes his supply for half an hour at the time when the demand is a maximum will cost you as much as a consumer who takes the same supply during seven or eight hours, provided those hours are the hours when the demand falls short of the maximum. You must keep your machinery running, and the only difference between running with a fair load and a light one is a small addition to your coal bill. Again, although there are many meters which will measure electricity, they are more or less costly, and sufficient time has not yet elapsed to test them for wear and tear. . . . I should, therefore, advise at first, at

all events, that you should charge by agreement with the customer. The basis of this agreement should be the maximum which the customer will take. You would put an instrument upon his service main which would cut him out if he seriously exceeded his maximum. With regard to the hours of work, Dr. Hopkinson considers that it would be best to begin by running from a little before sundown until perhaps one or two o'clock in the morning. The hours could be extended to an extent justified by the demand. In his judgment, the Corporation should not undertake the fitting up of houses for the electric light; but it should keep the most absolute control over the way in which the wiring is done." We shall probably have something more to say regarding this matter.

Electric Lighting in France.—The town of Saint-Fargeau (Yonne) has obtained an installation of electric lighting in virtue of an annual subvention of 2,000fr. voted by the municipality, and in consequence also of the support of M. Tusseau, a manufacturing locksmith belonging to the town. The motive power is obtained from a neighbouring watercourse. The town of Grenoble-sur-Garonne, also, recently inaugurated a central station, working 500 incandescent lamps; the installation having been carried out under the superintendence of M. Bonnet, the engineer, and M. Jougla. In reference to the central station at Nancy referred to in our last issue, we are able to supply the following additional particulars. The installation comprises three steam engines, each of 150 h.p., of which two are in use at the same time. These actuate respectively the alternating and the continuous current dynamos, the system of distribution employed being dependent upon the distance of the lamps from the station. As yet, only 900 lamps are in operation. Special terms are granted to the cafes making use of the light. The works are established in what was formerly a convent, and more recently a military barracks, the premises being let to the town for 1,000fr. per annum. The greatest activity prevails in relation to this enterprise, the concession for which was granted by the Municipal Council mainly with the view of obtaining a reduction in the price of gas. Hitherto, however, no such reduction has been rendered necessary; for, strange to say, instead of diminishing, the consumption of gas has augmented since the opening of the electrical works; thus, for the month of January last, it was 10 per cent. greater than in the corresponding month last year, that is higher than it has ever been previously.—The theatre at Claremont-Ferrand has for some weeks past been lighted by electricity. The installation comprises a 16 h.p. double cylinder Otto gas engine, an Edison dynamo, a set of accumulators, and 130 Edison lamps of from 10 to 20 candle-power, distributed on the stage and in the various offices. A Pieper arc lamp, placed above the entrance, is worked during the *entr'actes*. Besides the sum of 25fr. per night paid by the director of the theatre for the illumination of the stage, the contractors for the lighting—who are none other than the Gas Company—receive from the town an indemnity of 30fr. per night for a minimum of 100 performances per annum.—It is announced that a central station will shortly be opened at Mende. A first trial of the lighting at the Hotel de Ville was made at the end of January last, and it is expected that the works will be completed within a month. This station, the establishment of which was projected several years ago, is due to the labours of M. Lamy. It is to provide both for private and public lighting—the town of Mende being one of the few prefectures which have not yet been supplied with gas.

TRANSFORMERS OR ACCUMULATORS?

The subject of electric distribution by alternating currents and transformers has occupied the Institution of Electrical Engineers for three evenings, and, as usual, the discussion contained a good deal of useful matter, besides a certain amount of information or opinion which might be called irrelevant. The latter did not, however, preponderate, and, as far as it went, was rather instrumental in imparting a more lively tone to the proceedings. When new and special subjects come before a learned society, there are probably not ten members out of every hundred who are able to speak strictly to the point. In the present instance it was rather creditable to the remaining ninety that they did not unduly spin out the discussion by general talk, and so waste the time of the meetings. A little leavening of the heavy scientific arguments of the specialists is, however, not objectionable, and of such leavening there was just sufficient. The object of societies like the Institution of Electrical Engineers is mainly practical. Papers are read and discussed not so much with a view to advance pure science as with the object of showing how scientific discoveries may be practically applied for business purposes, and as this object is more or less attained, so must we consider the papers and discussion more or less useful, irrespective of their merits from the point of view of pure science. The question, therefore, is what useful lesson did the last three meetings of the institution teach electrical engineers?

Viewed in this light, last week's discussion was far more useful than that of the previous week, and even than the papers which provoked it. Mr Kapp's paper showed what could be done by transformers, whilst Mr. Mackenzie's paper described what had actually been done. Both subjects are of importance in themselves, but of far greater importance is it to know what place the transformer system occupies when compared with other systems of distribution, and it was this comparison which gave special value to last week's discussion. We do not propose to review the discussion in this place, as we shall in due course report it at some length, but we may draw some practical conclusions from the remarks made by the various speakers. Briefly described, the discussion was a contest between the advocates of distributing electricity by means of continuous currents and secondary batteries on the one hand, and the partisans of distribution by alternating currents and transformers on the other hand. Direct supply from the dynamos to the lamps was necessarily excluded, because neither of the rival systems would be used in central station lighting when the area of supply is limited. In such cases there is no need to employ high tension currents, and, therefore, no need to use transformers, although storage batteries would undoubtedly be of advantage. They would be used not for the purpose of reducing the quantity of copper in the mains, but simply as a precaution against interruption in the supply through an accident to the machinery, and also to enable the machinery to work at full output for longer periods, a condition of working which evidently secures greatest economy as far as the engines and dynamos are concerned. Whether this increase of economy will not be more than counterbalanced by the waste of energy in the batteries and by the cost of renewal of plates, is a matter which depends entirely on the perfection of the particular battery employed. Up to the present, the system has not been adopted to any large extent. As far as we know, it is not used in central station lighting in America; and in Europe there are, we believe, only five stations so worked—one in Kensington, two in Berlin, one in France, and one in Vienna. In the four first-named installations the batteries do not act as transformers for toning down the high pressure of the dynamos to the 100 volts or so, required by the lamps, but in the Vienna installation the batteries perform this function. The high pressure service there is at between 100 and 500 volts, and the batteries are divided into four groups, each supplying separate sets of lamps at 100 volts. The fact that out of the many hundred central stations only a very few use storage batteries seems to show that up to the present, at all events, those responsible for the erection and working of these stations either

do not consider batteries necessary, or if they recognise their usefulness, have not sufficient confidence in them to incur the expense of their adoption. We are inclined to think that the latter is the true reason. Once let it be proved that storage batteries are perfectly reliable, fairly efficient, and not too dear, and their adoption for central stations working at 100 volts, or a little over, will be secured. There is an enormous field for the makers of secondary batteries. It is an open secret that profits on the manufacture of dynamos have of late declined almost to the vanishing point. The competition is exceedingly keen, and customers are very exacting. To put it bluntly, the market is spoilt. With batteries this not so. There is hardly any competition, and buyers of these appliances have as yet had no opportunity to become hypercritical. They are easily satisfied, and will remain in this complacent frame of mind until the perfect battery has been invented. Whoever is first in the field with a really good, even if not perfect, battery will reap a golden harvest.

Having admitted the importance of batteries for a central station supplying only home circuits—that is, circuits extending only to such moderate distances as can be supplied on the direct low tension system—let us see how the case stands with long distance service. In the first place, it must be borne in mind that the batteries would have to be charged from a high tension current, and here we are at once confronted with two difficulties. One is the insulation of the batteries from earth, and the other is the dynamo itself. When the difference of potential between the first and last cell of a battery is only 100 volts, the insulation presents no great difficulty, and in many cases no further precaution than placing the cells on wooden stands is used. But when ten or twenty of such batteries are charged in series, the potential difference between the first and last cell in circuit will amount to 1,000 or 2,000 volts, and although the batteries may be miles apart, their tendency to leak to earth must obviously be the same as if all stood in the same room. To place the cells on wooden shelves would in this case be insufficient insulation, and it would obviously be necessary to use some high class oil insulator. This can be done at some little expense, but there is another difficulty of insulation to be faced. If each battery is coupled to its own lighting circuit whilst the charging current is on, the leak would take place between the lighting circuits and earth, and, moreover, it would be highly dangerous to touch any part of the lighting circuit. It will therefore be necessary to disconnect the lighting circuits from the batteries whilst the latter are being charged, and as the supply of current cannot be interrupted, it follows that duplicate sets of batteries must be employed. We have assumed above that all the batteries are charged in series, but our reasoning also applies to batteries charged in parallel, an arrangement which will be preferable for working in connection with a network of street mains, because a failure of one battery would not entail extinction of the lights ordinarily fed by it. But assuming that we have installed a sufficient number of duplicate batteries at various points of the network, that we have insulated each battery from earth in an absolutely reliable manner, and that we have provided interlocking switches of such construction that it is impossible to couple any battery being charged to the lighting circuit,—we have yet to provide a charging dynamo. Now this dynamo should have a high efficiency, and work without sparking. Is there such a machine in the market? We doubt it. Prof. Silvanus Thompson pointed out that an ordinary gramme commutator is quite unsuitable for use with an armature giving 1,000 or 2,000 volts. For such pressures we must use a Thomson-Houston, or a Brush machine, either of which has necessarily a lower efficiency than any of the better low tension machines now in the market, and probably also a lower efficiency than modern alternate current machines. Mr. Crompton proposes to limit the pressure to 500 volts, as he has done in the Vienna installation, and to work the lamps from a subdivided battery, which might or might not be charged at the same time. If a good earth occurred at one end of his battery, a person touching the lamp wire connected to the other end would receive a shock of 500 volts, and, although this may not be fatal, we doubt whether

consumers would care to run the risk. But apart from this consideration, if the limit of 500 volts be adopted, it is evident that the battery system of distribution will only be applicable over comparatively small districts, and cannot, therefore, compete with the transformer system using currents at 2,000 volts or more. To bring the two rival systems upon even terms, we must assume the pressure to be the same in both, and, therefore, Mr. Crompton's simple plan of charging and lighting at the same time becomes impracticable. This does not, however, preclude the use of batteries for long distance central station lighting. We have sufficient confidence in modern electrical engineering to expect that by degrees all the various difficulties we have enumerated will be overcome and perfect batteries will be available. Then and only then will it be feasible to distribute electricity by high tension continuous currents. But what is to be done in the meantime? Are we to abandon all ideas of central station lighting other than by home circuits extending only a few hundred yards from the dynamos? Obviously not. We can work with alternating currents to any reasonable distance, and, having these means ready to hand, it would be folly to let business go by whilst waiting for a more perfect system. The programme laid down by Mr. Kapp in his paper is reasonable because making provision for the adoption of the more perfect system when this becomes available. He advocates the laying down of a complete network of mains as used in direct supply stations. At certain points there would be fixed large transformers feeding this network, so that only low tension wires need enter the houses of consumers. If the change becomes possible these transformers would be replaced by storage batteries, whilst the alternate current machines at the station would be exchanged for high tension continuous current dynamos. The station buildings, boilers, engines, and mains would, of course, be retained without alteration. Thus the change would be effected with a minimum of loss in discarded plant.

ELEMENTARY TESTING SUITABLE FOR ELECTRIC LIGHTING SYSTEMS.

BY THOMAS GRAY, B.Sc., F.R.S.K.

[All rights reserved.]

(Continued from page 129.)

As has already been pointed out, boxes of resistance coils can not be used for the accurate measurement of small resistances, and in order to get to some extent over this difficulty, Sir William Thomson constructed boxes of conductivities. The conductivity, or conductance as it has recently been called, of a coil is the reciprocal of its resistance, and

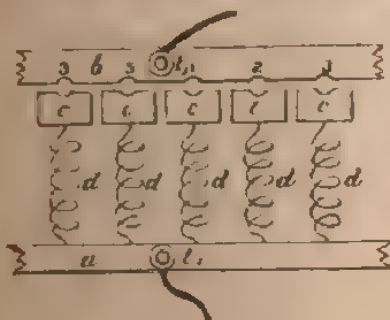

FIG. 7.

hence is proportional to the cross section of the wire forming the coil. In order to add conductances, therefore, we must add to the section of the conductor, that is to say, we must put the coils in parallel or multiple arc. The arrangement is illustrated in Fig. 7, in which *a b* represent two heavy bars of copper or brass (in Sir William Thomson's box these bars are of brass and are about one square inch in section), *c c c* are blocks of the same substance fixed to the cover of the box in such a way that they can be put in contact with *b* by means of plugs as in an ordinary resistance box. The conductances *d d d* are soldered at one end to the bar *a*, and at the other end to the blocks,

c c c. They are wound on bobbins, and are in every way similar to ordinary resistances, except that they are made of much thicker wire. The conductances are expressed in reciprocals of ohms—that is to say, a conductance of 1 is a resistance of 1 ohm; a conductance of 10 is a resistance of $\frac{1}{10}$ th of an ohm, and so on. The conductances introduced by the different plugs are marked in the same way as the resistances in the ordinary boxes; and the resistance of a wire, measured by this box, is obtained by taking the reciprocal of the sum of the conductances in the box when balance was obtained in the test. This arrangement suits well for the measurement of resistances of from one ohm downwards, but for resistances much higher than that the method becomes insensitive, unless the box is so large as to be inconveniently heavy and expensive. The method has the great advantage that there are no needless contact

FIG. 8.

resistances in the circuit, and the result is only influenced by contact resistance in the proportion that the different contacts influence the conductance of their own circuits. The terminals *t₁ t₂* must be massive, and kept perfectly clean. For the measurement of high conductances they are preferably made of cups of mercury.

The combined arrangement for the measurement of resistances and conductances recently introduced by Sir William Thomson, and called a "mho ohm drum," is illustrated in Figs. 8 and 9. Fig. 8 shows a plan of the top of the drum, and Fig. 9 a section showing how the resistances are joined to the contact pieces, and how these pieces are arranged.

FIG. 9.

Two heavy rings of copper, *a* and *b*, are fixed concentrically to the top of the cylinder, which is a disc of vulcanite. Between these rings a series of brass or gun metal tubes with heavy flanges, *c c c*, are fitted into the vulcanite and secured by nuts, *g*: into these tubes gun-metal knurled pieces, *c c c*, are fitted, and held firmly in position between a shoulder bearing on the upper side of *c*, and a steel pin *h*, bearing on the lower end of the tube. Beneath the upper bar of *c* a spring, consisting of several thicknesses of thin, hard copper, is soldered; and into the end of *c*, and over the end of the spring, a handle, *f*, with a cam shaped end, is pivoted. The resistance *d* is usually made of well-insulated

platinoid wire, and is wound on a cylinder of copper on the outside, of which a series of copper rings are soldered, so as to form channels for the coils. The channels for the coils are covered with several thicknesses of varnished paper to secure insulation, and the wire is well dried, and drawn through melted paraffin as it is wound on. Outside the coils, and in contact with the copper division rings, another cylinder of copper is placed, and screwed to several of the copper rings to secure good contact. The object of the copper cylinders and copper dividing rings which joins them together is to secure rapidity of cooling, so as to insure small error due to the heating of the wire by the current passed through it. When this drum is used as an ordinary resistance box the rings *a* and *b* form the terminal plates, and the beginning and end of the resistance inserted in the box are put into contact with these rings by means of the proper crank pieces *e*, springs *h*, and cam handles *f*. Between these two terminal contacts the contacts are all made on the flanges of the tubes *c*. The contacts are made by turning *e* to the proper position, and pressing the spring *h* firmly into contact with *e* by means of *f*, and they serve, like the plugs in Figs. 4 and 5, to cut out resistances by short circuiting them. The resistances are connected to the contact pieces *e* through a flexible strand *i*, which is

whole of the others can be tested against it without any contact resistance or other uncertainty being introduced.

To use this drum for the measurement of conductances the contacts have to be made on the rings *a* and *b*. The arrangement only differs from that shown in Fig. 7 in not having the coils permanently connected to *a*. Fig. 8 shows the connections for placing the resistances 32 and 512 in parallel—that is, for adding the conductances $\frac{1}{32}$ and $\frac{1}{512}$ together. The resistances, 64, 128, and 256, are cut out by making the contacts from *A* and *B* on the same ring, and a similar method would be followed for any other case. The adoption of this combination adds very little to expense of the set of resistances, and, as will be readily seen, greatly increases the range of accurate measurement. A resistance of 1 ohm, for example, can be measured directly to within $\frac{1}{8000}$ th of its true amount by means of a box the total resistance in which is 8,000 ohms; whereas by the ordinary box there is nothing between 1 ohm and 2 ohms. With a box containing a maximum resistance, *R*, or a total resistance, $2R$, the least sensibility for direct measurement is for a resistance equal to \sqrt{R} , and the sensibility is equal for both methods of using the box. This mho-ohm drum is usually combined with two other sets of resistances, not shown in the drawing, for the purpose of forming, together

The Blakey-Emmott Dynamo.

soldered to the end of *e*, and is prevented from sustaining damage by overtwisting by stops which prevent *a* making more than half a turn. The tube *c* and the crank piece *e* are connected by a flexible piece *i*, which prevents error due to resistance in the contact between *e* and *c*. It will be observed that there is in this arrangement only one contact for each resistance cut out, namely, that between the spring and the plate *c*, instead of two, one on each side of the plug, in the plug method. This method possesses also the great advantage that the contact surfaces can be very easily cleaned. They may, in fact, be made self-cleaning by pressing down the spring with the cam, and then turning *e* backwards and forwards. There is besides the advantage that the whole of the box does not require to be in the circuit, because any part can be included between the terminal plates. The magnitude of the resistances are made in the geometrical series 1, 1, 2, 4, 8, &c., each resistance being in this way equal to the sum of all that precede it. The figure shows a drum, having a total resistance of 1,024 ohms; but a very few additional contact pieces would serve for a box of very high resistance. The advantage of making each resistance equal to the sum of those that precede it is, that the resistances can readily be tested against each other. Thus, if the one ohm be standardised at any time, the

with the drum, three of the four resistances in Wheatstone's bridge arrangement.

(To be continued.)

THE BLAKEY-EMMOTT DYNAMO.

This dynamo, which we illustrate above, is made by Messrs. Blakey, Emmott and Co., of Halifax. The magnet, which has the poles at the top, consists of a single U-shaped forging. The makers claim a considerable advantage from this, as it avoids both the use of cast iron and the magnetic resistance of joints. The armature, which is of the Gramme type, is built up of thin insulated discs of annealed iron, mounted on a gun metal spider. This spider is securely keyed to a steel shaft, thus ensuring positive mechanical driving. In the machines intended for incandescent lighting there is only one layer of wire on the outside of the armature. The commutator consists of copper, specially hard drawn to the required section, and mica is used as an insulator. Special brush holders are used, each separately adjustable, and with hold-off catches. In all sizes of machine above the No. 2 (for 50 lamps) at least two pairs of

brush-holders are provided. The rocking bar which carries the brushes can be readily moved to bring them to any desired point on the commutator. The brushes themselves are made of thin copper ribbon. The machine is mounted on a strong cast-iron base, and the bearing standards are bushed with gun metal. Light feed lubricators are used, and special means are provided for carrying off used oil from the bearings. The machine

of electrical work which is being done in London and other parts of the country, and there is no doubt that it will increase rapidly within the immediate future especially when the Electric Lighting Act has been amended.

Of the engines which have become favourites amongst electric light engineers are those made by Messrs. Robey and Co., Messrs. Marshall, Messrs. Davy, Paxman and Co., Messrs. Hornsby and Sons, Messrs. Allen, Messrs. Galloway,

FIG. 1.—Diagram Robey's Compound Engine.

in the illustration, called the No. 3 size, is intended for an output of 6,000 watts, or 100 volts and 60 amperes, at 1,150 revolutions per minute. It is compound wound for constant potential. The resistances are: Armature = $\cdot 059\omega$, series coils = $\cdot 015\omega$, shunt coils = 53ω . The electrical efficiency at full load is 92.7 per cent. The total weight of copper is 132 lbs.; and in the armature alone, 13 lbs. This gives an output of 48.5 watts per pound of copper in the whole machine, and 457.6 watts per lb in the armature only. The total length of wire on the armature is 291.6 ft., which is at the rate of 35 in. per volt. The total strength of useful field is 432 lines—English measure. These machines run without sparking, and do not heat after long runs. Messrs. Blakey, Emmott and Co. (Limited) are now constructing this type in varying sizes, intended for outputs of from 600 to 120,000 watts.

MESSRS. ROBEY & CO.'S COMPOUND "ROBEY" ENGINE.

Since the commencement this year of the publication of a new series of the *Electrical Engineer*, the number of subscribers has been so much increased that far the larger

Messrs. Hick, Hargreaves and Co., and others, and as we happen to be first prepared with engravings of one of the engines of the former as used at the Newcastle Exhibition last year, we give that first. Of these engines there were eight of about 100 indicated horse-power each, and two horizontal engines. A horizontal engine by the same firm, with the Proell cut-off gear, was used for driving the machinery in motion.

The engine which we illustrate is a compound engine with cylinders of 12 in. and 21 in. diameter, and a stroke of 24 in., the normal speed being 100 revolutions per minute. It is fitted with Richardson's governor and radius link automatic cut-off gear, by which a practically uniform speed is maintained under varying load. This gear is clearly shown in the perspective view which we give on page 204, and its efficiency may be gathered from the indicator diagrams which we give herewith. The steam pressure employed was 120 lb. per square inch, and when the diagrams (Figs. 1 and 2) were taken the load was rather light, as shown by the early cut-off seen in the high pressure diagram. The expansion line of the diagram (Fig. 1) may be considered perfect, and no improvement can be desired in the low pressure diagram, which is necessarily of a form very different from that from the high pressure cylinder, inasmuch as the former receives its steam from the limited

LOW PRESSURE CYLINDER

FIG. 2.—Diagram Robey's Compound Engine.

proportion must find it impossible to refer to back numbers for any information published before the present year. It is our intention, therefore, to illustrate and describe the several forms of engines most in use for driving dynamo-electric machines for lighting and power transmission, and it becomes increasingly necessary that we should do this, because the number of engines likely to be required for electric lighting is now rapidly increasing. Few people have any idea of the very great amount

supply of the high pressure cylinder and intermediate receiver. The high pressure diagram (Fig. 3) was taken when more work was being done, but it will be seen that the admission, cut-off, and expansion, are all equally perfect, the cut-off being exceedingly sharp and the expansion line correspondingly close to the theoretical curve. The wavy line in the expansion curve, especially in the left-hand diagram, is due partly to the oscillation of the indicator parts, and perhaps also partly due to the condensation and re-

evaporation of steam in the first stage of the expansion. We are informed that repeated tests of these engines have given a consumption of under 2lb. of Welsh coal per indicated horse power per hour, or under a ton of coal for 100 horse-power for 10 hours.

FIG. 3.—Diagram Robey's Compound Engine.

Such a result could not, of course, be obtained without a first-class boiler as well as engine, and the locomotive type adopted is no doubt the best for the purpose. The workmanship of boiler and engine are of the highest class, as our readers are aware, and with the high pressure now used none but the best boiler making will suffice.

FORMULÆ FOR TRANSFORMERS.*

BY PROFESSOR GEORGE FORBES, F.R.S. (L. AND E.)

The modern transformer for electric lighting is an induction apparatus in which the primary coil is of high, and the secondary of low, resistance, consisting of two ring coils of insulated copper wire enclosed in an iron sheathing, so subdivided as to prevent the formation of local currents in the iron when subjected to the influence of alternating electric currents in the coils. The terminals of the primary are kept at a constant mean difference of potential. The secondary circuit includes the lamp circuit, and is of varying resistance. The iron is so situated with respect to the coils that there is no free magnetism; this simplifies the mathematical treatment of the phenomena.

It is required to predict (1) the magnetic induction in the iron, (2) the work given off to the lamp circuit, (3) the whole work absorbed by the apparatus, (4) the waste of energy when no lamps are in circuit, and (5) the effect which will ensue from varying the construction of the apparatus. The first of these has been approximately solved on the assumption that the permeability of the iron is constant.†

It is generally assumed that in such a system of electrical distribution the electromotive forces, the electric currents, and the magnetic induction are simple harmonic functions of the time. This would not be the case if the phenomenon called by Ewing "magnetic hysteresis" is taken into account, and in a preliminary investigation this must be omitted. Its effect in practice is insignificant so long as the magnetic induction in the iron is not high.

The notation now adopted is as follows:—

- p_1 = number of turns in the primary coil.
 - p_2 = " " " secondary coil.
 - r_1 = resistance of the primary coil.
 - r_2 = " " " secondary circuit, including lamps.
 - c_1 = current in the primary circuit.
 - c_2 = " " " secondary circuit.
 - m = integral of the induction over the cross-sectional area of the iron.
 - ρ = mean length of lines of induction in the iron.
 - a = cross-sectional area of iron \times permeability.
 - n = $\pi \times$ number of alternations of E.M.F. per second;
 - $= 2\pi \times$ " " complete periods of E.M.F. per second.
 - w_1 = work done in unit time by the primary current.
 - w_2 = " " " in the secondary circuit.
 - e = difference of potential of primary terminals.
- C.G.S. units are adopted throughout.

* Paper read before the Society of Telegraph-Engineers and Electricians on the 9th February.

† J. Hopkinson, Proc. Roy. Soc., 1887.

$$\text{Assume } m = M \sin nt \quad (1)$$

$$\text{then } c_2 = -\frac{p_2}{r_2} \frac{dm}{dt} = -\frac{M n p_2}{r_2} \cos nt \quad (2)$$

$$\text{and } w_2 = \int_0^1 c_2^2 r_2 dt = \frac{M^2 n^2 p_2^2}{r_2} \int_0^1 \cos^2 nt = \frac{M^2 n^2 p_2^2}{2 r_2} \int_0^1 (1 + \cos 2nt) dt$$

The mean value of the periodical part is zero. Hence

$$w_2 = \frac{M^2 n^2 p_2^2}{2 r_2} \quad (3)$$

$$\text{Again, } M \sin nt = \frac{4}{\pi} (p_1 c_1 + p_2 c_2);$$

$$\text{whence } c_2 = \frac{M \rho}{4 \pi p_1} \sin nt + \frac{p_1^2 n M}{p_1 r_2} \cos nt \quad (4)$$

$$= C_1 \sin (nt + \alpha),$$

$$\text{if } C_1 \cos \alpha = \frac{M \rho}{4 \pi p_1} \text{ and } C_1 \sin \alpha = \frac{M p_1^2 n}{p_1 r_2}$$

$$\text{Again, } c_1 = \frac{E}{r_1} \sin (nt + \beta) - \frac{p_1}{r_1} \frac{dm}{dt}; \text{ if } e = E \sin (nt + \beta),$$

$$= \frac{E}{r_1} \cos \beta \sin nt + \left(\frac{E}{r_1} \sin \beta - \frac{p_1 M n}{r_1} \right) \cos nt \quad (5)$$

Equating coefficients in (4) and (5), we have

$$E \cos \beta = \frac{M \rho r_1}{4 \pi p_1}; \quad E \sin \beta = M n \left(p_1 + \frac{p_1^2 r_1}{p_1 r_2} \right)$$

$$= M n p_1 \left(1 + \frac{p_1^2 r_1}{p_1^2 r_2} \right);$$

$$\text{whence } \frac{E^2}{M^2} = \left(\frac{\rho r_1}{4 \pi p_1} \right)^2 + n^2 p_1^2 \left(1 + \frac{p_1^2 r_1}{p_1^2 r_2} \right)^2 \quad (6)$$

$$\text{also, } w_1 = \int_0^1 c_1^2 r_1 dt = C_1^2 E^2 \int_0^1 \sin^2 (nt + \alpha) \sin^2 (nt + \beta) dt$$

$$= \frac{C_1^2 E^2}{2} \int_0^1 \{ \cos (\alpha - \beta) - \cos (2nt + \beta + \alpha) \} dt$$

$$= \frac{C_1^2 E^2}{2} \cos (\alpha - \beta) = \frac{C_1^2 E^2}{2} (\cos \alpha \cos \beta + \sin \alpha \sin \beta)$$

$$= \frac{M^2}{2} \left\{ r_1 \left(\frac{\rho}{4 \pi p_1} \right)^2 + \frac{n^2 p_1^2}{r_2} \left(1 + \frac{p_1^2 r_1}{p_1^2 r_2} \right) \right\} \quad (7)$$

$$= \frac{E^2}{2} \cdot \frac{r_1 \left(\frac{\rho}{4 \pi p_1} \right)^2 + \frac{n^2 p_1^2}{r_2} \left(1 + \frac{p_1^2 r_1}{p_1^2 r_2} \right)}{\left(\frac{\rho r_1}{4 \pi p_1} \right)^2 + n^2 p_1^2 \left(1 + \frac{p_1^2 r_1}{p_1^2 r_2} \right)} \quad (8)$$

When the actual figures pertaining to a modern transformer are inserted, it is found that the quantity $\frac{p_1^2 r_1}{p_1^2 r_2}$ is less than .01; that the first term of the numerator in (8) is small compared with the second; and that the first term of the denominator is very small compared with the second.

The efficiency is found by dividing (3) by (7).

When no lamps are used on the secondary circuit, the rate of work done is, by (7) (r_2 being infinite),

$$\text{waste} = \frac{M^2}{2} r_1 \left(\frac{\rho}{4 \pi p_1} \right)^2$$

It will be noticed that the efficiency of the apparatus depends on the first term in (7) being small compared with the second; hence n (or the number of alternations per second) may be diminished without loss of efficiency if ρ be diminished, or if the mass of iron be increased.

LIGHTING AT THE BRUSSELS EXHIBITION.

In order to make a special feature of the lighting, as of the telephonic service, the executive committee has entrusted all the arrangements for the former to one of its members, M. Charles Moulon, with the assistance, as "ingenieur, chef de service," of M. A. Bandsept. The committee has asked the co-operation of the principal electric lighting companies and contractors in Belgium and other countries; and arrangements have been so made that the greatest possible number of competitors may engage in lighting

the buildings and gardens. The lamps will be supplied gratis, but will compete for several valuable prizes, other special prizes being offered for lamps working under exceptional conditions of yield and economy.

Among the Belgian participants in this lighting contest are the Phoenix Company of Ghent, M. Dulait Fils, of Charleroi; MM. Bouckaert et Cie., Herr Eduard Rau, representative of Siemens and Halske, of Berlin; M. Goffin, director of the Société Industrielle d'Electricité, Brussels; M. Pieper and MM. Gerard et Cie., of Liège, who intend to lay down a distant transmission like that they established between the Laeken Gasworks and Brussels Opera House, for lighting its stage. Among the most important participants out of Belgium are the Société Suisse d'Electricité, of Lausanne; Mr. Bury, of Manchester, the Bernstein Company, of London; the Compagnie Cuenod et Sautter, of Geneva; Ganz and Company, of Buda Pesth; the Gulcher Company, of London; the United Electrical Engineering Company (Jablochhoff), London; the Thomson-Houston International Electrical Company, of Boston; and the Anglo-American Brush Electric Light Corporation, of London, who will light the British section of 15,000 sq. m., or 161,465 sq. ft. area.

The project for lighting the exhibition comprises three distinct parts—that by electricity of the buildings and annexes; that of the façades and fountains; and that of the gardens, provisionally by gas supplied gratis by the Brussels Municipal authorities, and eventually by electricity. The great object kept in view has been to afford a contrast between a divided light, spread in profusion over the plantations, kiosques, &c., in the park on the one hand, and the sober grandeur of a concentrated light illuminating the buildings in the background.

The exhibition buildings embrace two rectangular pavilions, as they are called, which were built for the National Exhibition of 1880; one will be devoted to retrospective fine art and the other to fêtes and ceremonials. They are connected by a circular colonnade of more than 200 metres length; and in the middle will be erected the King's Pavilion. The Grand or Machine Hall, situated behind the colonnade and King's Pavilion, is 250 metres = 820 ft. long, 6m. = 223 ft. wide, and 23m. = 75 ft. high. Two annexes, 100m. = 328 ft. long by 60m. = 197 ft. wide, terminate this portion.

The lighting of the Machine Hall will be effected by 84 arc lamps chosen from the systems of Piette and Krizig (Bouckaert et Cie), Dulait (Soc. An. Electrique et Hydraulique), Thomson-Houston, De Puyt, Jaspar, and Pild (Soc. An. Electr. et Hydr.). According to the nature of the installation adopted for the engines and the metallurgical exhibits, the Machine Hall will be lighted, either with fifteen 2,000-c. arcs in the central avenue and thirty-two 1,500-c. and forty 1,200-c. arcs disposed in the lateral compartments, or thirty large arcs arranged in groups of five at the ends of the hall, with lamps of less intensity grouped about the middle of the hall. These lamps will be hung at heights varying from 7 to 10 metres, that is to say, from 23 to 33 feet, and at distances apart of 10 and 16 metres, or 33 and 52 feet.

The wings of the Machine Hall, 15m. or 50 ft. high only, will be provided with *lustres*, or, as we call them, "chandeliers"—the English and French just transposing the signification to these two terms—with incandescent lamps, alternating with small arcs of 4 amperes, and incandescents of 24 volts and 6½ amperes. The Salle des Fêtes, of nearly 3,000 sq. m. = 32,000 sq. ft. superficial area, will form the subject of a special scheme for which several electricians have submitted plans and estimates. The lighting will in all probability be effected by ten or twelve 12-ampere arcs, while groups of Edison and Swan, Victoria, and other incandescent lamps will be disposed in the space between the columns.

The interior of the King's Pavilion and the lateral colonnades will be lighted by six to eight large arc lamps; while the back will be lighted by the reflection of two 3,000-c. lamps mounted in the roof framework. The balconies will be lighted by 30 to 50-c. Bernstein lamps, supplied by current from a distance in accordance with this inventor's system. The colonnade connecting the central pavilion with the main building will stand out from the rest of the structure, owing to the white light distributed in profusion between the colours.

This light will be supplied by Thomson-Houston lamps, 10m. = 33 ft. apart, placed aloft and completely hidden from view. Four 3,200-c. arcs, with reflectors, furnished by MM. Bouckaert et Cie., will be placed at the bottom of the slope for throwing a pencil of white rays on the two pavilions in the foreground, so as to bring out the architectural features of the façades.

At the front end of the gardens two "hydro-electriferous pylons," on the Dulait system, 25m. = 82 ft. high, and giving out a light of 5,000 candles each, will mark the main entrance. This installation, quite new of its kind, will greatly contribute to enhance the effect of the general illumination, which will extend the whole length of the Rue de la Loi. The annexes of the central hall will be lighted by 38 De Puyt, Dulait, and Piette et Krizig arcs, of an intensity varying from 350 to 900 candles for the right hand annexe, and thirty 8-amp. Ganz arcs for that on the left hand of 2,400 sq. m. = 25,834 sq. ft. available area. This distribution of light, one lamp, 5m. = 16 ft. high, for every 80 sq. m., or 861 sq. ft. of area, answers to 28 candle-metres of mean intensity—that is to say, a light about equal to that in the Machine Hall. Eight Thomson-Houston 2,000-c. arcs, 18m. = 59 ft. high, will light up the garden in front of the annexes. Finally, several powerful lamps will be disposed along the avenue from the main entrance to the ornamental stone balustrade in front of the building.

All this aggregate of illumination will only require 350 h.p., given by the motors in the Machine Hall, 150 h.p. remaining available for lighting the façades of the pavilion erected in the centre of the semicircle. In fact, the motors in the machine hall will yield nearly 800 h.p., of which 500 h.p. are available for lighting purposes. The main shaft is 16 c.m. = 6¼ in. in diameter, and will make 110 revolutions per minute, the countershaft for the dynamos making 250 revolutions. The yield of, and power required by, the various lamps, are estimated by the authorities as follows:

Aras.	Nom. c.p.	H.-P. required.
Piette and Krizig.....	3,500	1.50
" "	1,400	1.06
" "	1,200	0.85
Thomson-Houston	2,000	1.00
" "	1,400	0.75
Dulait	2,200	1.40
" "	1,800	1.30
De Puyt	2,000	1.50
" "	700	0.75
Incandescents,		Lamps per h.p.
Bernstein	35	10.5
Victoria	16	10
Edison	16	10

The illumination of the fountains will be confided to Galloways or Sennett and Pieper, in which latter case the system will include a portion of the main walks of the garden. The two installations will be so combined as to work alternately, in order that the motive power necessary for the jets and the illumination of the fountains may be also utilised for contributing to the general illumination, for which purpose a 150 h. p. engine will be erected in one of the wings of the Aquarium. The Aquarium, the Kursaal, and the Bierhalle will be lighted by Pieper, of Liège, while the English section will again receive its Manchester installation. Lastly, the gardens, plantations, and kiosques will be lighted by 25,000 gas jets arranged in garlands along the walks and in the shrubberies. MM. Gerard et Cie will probably undertake the electric lighting of the Rue de la Loi, their installation constituting the first industrial demonstration in favour of the adoption of the electric light for public illumination.

Society of Arts.—On the Saturday afternoons, March 10 and 17, at 3 o'clock, Prof. Lodge, F.R.S., will deliver two lectures, on the "Protection of Buildings from Lightning." Two other electrical papers are promised, but the dates are not yet fixed when they are to be read: one "On the Measurement of Electrical Currents," by Prof. G. Forbes, F.R.S.; and the other by Mr. R. E. Crompton, "On Electric Lighting from Central Stations."

MESSES. ROBEY AND CO.'S COMPOUND "ROBEY" ENGINE. (For details see page 201.)

THE ELECTRICAL ENGINEER.

Published every Friday.

Price Threepence; Post Free, Threepence Halfpenny.

Editorial and Publishing Offices:

139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. Special Terms for a series can be arranged on application.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at **THREE WORDS for ONE PENNY**, with a **MINIMUM** charge of **SIXPENCE**.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations, or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months.	6 months.	12 months.
United Kingdom	3s. 3d. ...	6s. 6d.	12s. 0d.
Within the Postal Union	4s. 4d. .	8s. 8d.	17s. 4d.
Other Places	4s. 10d. ...	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 we gave a Portrait of E. GRAVES, Esq., President of the Society of Telegraph Engineers, and stated our intention of giving a series of Portraits of eminent Electricians of the century. In fulfilment of our promise we have already issued a Portrait of W. H. WOLLASTON, M.D., F.R.S., who was in his scientific prime at the beginning of the century. This will be followed by SIR HUMPHREY DAVY, F.R.S., whose fame as an electrician is still more prominent than that of WOLLASTON. Portraits of Past Presidents of the Society are in preparation, and we hope soon to have ready that of PROF. D. E. HUGHES, F.R.S.

THE CITY AND ELECTRIC LIGHTING.

This article is directly intended to convey information to members of the Corporation and others who, daily leading busy lives, are not familiar with the various developments of electrical practice, nor the present position of electric lighting. Avowedly, then, the object is to influence the authorities to come to a decision favourable to the employment of electricity for lighting our streets and houses. It is necessary, in the first place, to get rid of the idea that no more light is needed than is given at present by the gas lamps. Those who argue that the present light is sufficient cannot be familiar with the facts, nor could they be persuaded to advocate or support any change. It is probable that, like Charles Lamb, they come into the City late and go away early. No doubt such a course is perfectly satisfactory to those able to do it, but the workers are in a different position, and as the profits made in the warehouses, factories, and shops are directly due to the labours of the workers, it is not difficult to see that whatever conduces to a greater amount of work being done in a given time is a matter requiring careful consideration. No one will deny that more and better work is done under the beams of the midday sun than by any means of artificial lighting yet devised. It is admissible, therefore, to assume that the light which approximates most nearly to sunlight is better than any rival illuminant. Part and parcel of the work of the City is the transmission of goods and passengers from one point to another. Surely it will be granted that the better the light the greater the expedition in loading and unloading goods and in the pace of the street traffic. Without troubling farther in this direction, it will be assumed that the more and the better the light distributed over the City the more is the economy of time and labour in the proceedings carried on therein. Thus, the questions presenting themselves somewhat forcibly to those who have to legislate for us as regards light are—Can we obtain more and better light at a reasonable cost for those who look to us to consider their interests? and, What kind of light can be so obtained? The question of cost is a little complex, as will be seen hereafter.

The problem before the City authorities at the present moment is whether it is better to replace gas by electricity, and upon their verdict much more depends than is at first sight seen. Taking the requirements of street lighting: there can be no two opinions as to the fact that with electricity you can get more light, and it is as emphatically proved that the light is a better light. It is ridiculous for those interested in gas to talk about the steadiness or unsteadiness of arc lamps as compared with the steadiness of street gas lamps. There is no such thing as steadiness in the latter, though there is in the former. When an arc lamp blinks it does so with a power of 800 or 2,000 candles;

when a gas lamp blinks it is with from 8 to 14 candles. The one is noticed and noticeable, the other has little or no influence upon the visibility of the darkness. With regard to atmospheric contamination, there is not much to be said in regard to street lighting one way or the other. If you burn coal under a boiler to generate steam to drive electric light machinery, you contaminate the air passing through the chimney shaft; with gas the contamination is more subdivided, that is all. It may be said that, if more light is required, it might easily be obtained by increasing the number of gas lamps or their brilliancy; by replacing, for example, each 14 c.-p. gas jet by one of 200 or 400 c.-p. No doubt that would in a measure get over the difficulty; but, unfortunately for the exponents of gas lighting, so far as economy is concerned, directly we come to "more light" electricity smites them hip and thigh. To compare the cost of an arc lamp of 800, 1,000, or 2,000 c.-p. nominal with a 16 c.-p. gas lamp is absurd; but the comparison is altogether in favour of the arc lamp when it is compared with an equivalent gas light.

Assuming then that more light is really required, it cannot be denied but that the electric light is better than gas, and we contend it is far and away cheaper. According to "Newbigging's Handbook for Gas Engineers," third edition, p. 209, the number of hours during which gas is burnt in a year, if lighted all night, is 4,327; if lighted at dark and extinguished at eleven o'clock the number is given as 1,808; if extinguished at twelve o'clock as 2,173. The worshippers of gas may, so far as we are concerned, say "more light" certainly, but extend the gas. Taking first 5 cubic feet per hour, as giving 16 candles, 250 cubic feet would give 800 candles; and 250 cubic feet would cost one-quarter of 2s. 6d. or 3s. or 4s., or whatever the price per 1,000 of gas, say 7½d., or, burning 1,808 hours per year, an annual cost of £56 10s. We have before us the actual cost of 200 c.-p. gas lamps in a midland manufacturing district given in the surveyor's annual report as varying from £13 16s. 8d. to £16 15s. 3d., say averaging £14, and this multiplied by 4 gives £56 as the cost of four 200 c.-p. gas lamps—that is 800 c.-p.—the equivalent of one arc lamp. This price depends greatly upon whether gas is burnt in one or more lamps to the candle-power mentioned. The amount £14 is for a 200 c.-p. lamp; the cost of the ordinary 14 or 16 c.-p. gas lamps is only £2 7s. 6d. for the year, so that if 200 c.-p. were obtained by increasing these lamps the cost would be between £29 and £30. The Brush Company offered the City a 2,000 c.-p. nominal arc lamp, which you may call if you like 800 c.-p. actual, for £26. Our contention then that electricity is cheaper than gas is, we think, justified. Increasing the light by increasing the consumption of gas means increasing the cost

proportionately. If more light is wanted, the only loophole in favour of gas, so far as we can see, is that very little more light is needed, not twice as much as is now given, otherwise the offer of the Brush Company is exceedingly advantageous, in that they give at least ten times the light for twice the money now paid. It is stated that the electric light would be placed in the streets at a loss to the contractors. However that may be, is it not the case that gas is so placed, and that the gas companies, if they had only the street lighting to supply, could not supply it at the price now paid? It is useless to argue upon a portion of a scheme. The contractors take into consideration the whole lighting of the district, and doubtless are fully warranted in charging a much lower price for lighting, which is but part of a whole, than if that particular part had to be carried out alone.

There is one point that those in favour of gas might well discuss; in fact, it is the only point where they might score a point in their favour, though this is extremely doubtful. We have, however, no wish to cry up electricity merely for the sake of so doing. We believe not only that it is the best light for street lighting, but that it is the only light entirely suitable for that purpose. The point we refer to as worthy of argument is the distribution of the centres of light. The opinion of experts would incline to a larger number of lower candle-power lamps in such a city as London rather than a smaller number of greater candle-power. The great question to settle is the *minimum* light, reckoned in candle-power, required at any one point, although it would be as well to agree also upon a maximum. The two being given, the distance apart of the lights, neglecting the effect of reflection, is easily ascertained. Summarising, then, we hold: (1) More light is required; (2) Electricity is cheaper and better than gas; and (3) That care should be taken in the distribution of the centres of light radiation.

THE BILL OF THE UNITED TELEPHONE COMPANY.

The apathy of public bodies is proverbial; but at length London seems fairly roused to the evils of overhead wires, and petition after petition has been lodged against the Bill promoted by the United Telephone Company. This Company has few friends outside its own offices—except its shareholders. The reason is not far to seek, in its attempts to ride roughshod over the pet prejudices of the ordinary Englishman. Overhead wires are, like matter in the wrong place, objectionable only under particular conditions; and those conditions hold in London and other large towns. Overhead *v.* underground wires should be a matter of supreme indifference to the United Company. They know, we all know after a fashion, that the State sooner or later will buy over

the telephone systems, and will have to pay a larger price for underground than for equal overhead installations. The commercial heads of the various telephone companies want to make as much money as they can while their hands hold the reins, and after then the deluge! Whatever system they adopt, the new brooms will find fault and sweep clean. If this should prove to be the case, any expenditure now carried out will be largely wasted; in that it will not have time to fructify to the extent it would do under ordinary circumstances.

Now for a *volte face*. We see no adequate reason for opposing the United Company's Bill, rather we see many reasons for heartily supporting it. Let it pass, let the work be carried out, let it interfere as much as possible with telegraphy; and the sooner will come the inevitable time when telegraphy and telephony will be systematically worked from one centre—the Postal Telegraph Department. Telephony is becoming more and more a necessity for commercial life. Its progress should not be hindered. If Jones of Dundee can talk with Smith of Glasgow, why should not Robinson of London talk with Brown of Birmingham? Surely there is no valid excuse for stopping an overhead wire going out countrywards, when we tolerate them by hundreds in crowded city streets. These wires are no more a nuisance in sparsely populated country places than are the telegraph wires.

CURRENT DISTRIBUTION OF THE NEAR FUTURE.

BY DR. LOUIS DUNCAN, JOHNS HOPKINS UNIVERSITY.

Outside of constant current systems, which may for the present be considered as occupying a permanent field apart from the others, the two rival systems of electrical distribution are the direct and alternating constant potential systems; the former using direct currents of low potential, the latter employing alternating currents of high potential, reduced to a lower potential at the points of consumption.

I have, on a former occasion, considered the efficiency of direct current generators under different conditions, and before taking up alternating current apparatus, I will consider briefly the relative value of the two systems.

For lighting alone, leaving out the possibility of the use of storage batteries, and considering solely the economy of distribution, the alternating system presents a number of advantages where we wish to supply an extended area with light. These advantages are well known. In the first place, the flexibility of the system is greater; and, in the second place, the cost of conductors is very much less. It is in this last item that the system possesses the greatest advantage, and it would seem that it is undoubtedly better than either the parallel or multiple series systems for lighting extended areas, where the lights are more or less scattered.

There are two comparative disadvantages, however, in the system. No alternating current motor has yet been invented that will work practically, and, even provided storage batteries are improved so as to allow of their extended use, the system cannot economically profit by the storage of electricity. As to the first disadvantage, I think that it will, in time, be overcome. The problem is a perfectly definite one, as there are no underlying impossibilities in the working of such a motor, and I have strong hopes that in the next year or so alternating current motors will be working as successfully and economically as continuous current motors are to-day.

But if I believe in the future of alternating motors, I also believe in the future of storage batteries, and when these can be economically used, the greatest comparative advantages of the alternating system are lost. The flexibility of the direct system will then be as great as that of its rival, while it will gain the great advantage of storage, allowing a station to supply two or three times the energy with no increase of plant or complexity excepting that due to the battery itself.

The plan to be adopted would doubtless be to establish sub-stations containing the batteries and regulating apparatus, each of these stations supplying an area determined by the circumstances of the case, with an attendant in charge of one or more such stations. Such a system would allow all the uses to which electricity can be applied, and under simple and favourable conditions.

Even under present conditions, if the company manufacturing the distributing apparatus had the right to manufacture storage cells and supply them at a slight advance over cost price, and afterwards renew them when necessary, I believe the storage system could be economically applied in some cases. For example, the I. h. p. cell of a well known company probably costs something like 7 dols. to make, taking lead at 5 cents per pound, and red lead and litharge at 6. For renewal we should allow, perhaps, one complete set of positive plates and 15 per cent. depreciation on the rest of the cell. This, subtracting the value of the old positives, would give not over 2.50 dols. a year for depreciation. If we take these figures we could, I think, work out a profit in some cases. It is the best that can be claimed for storage at present, unless I have over-estimated the repairs. It is needless to say, however, that these prices are not those which rule in the market at present.

I have seen lately, in an English journal, an article by Mr. Rankin Kennedy, in which he wishes to show that the alternating system would profit by the success of the storage battery. He proposes to have the cells at the central station, to charge them during the day, and, when extra power is required, to use them to drive the motor of a motor-alternating-dynamo apparatus which will feed into the main lines. I fail to see any particular advantage offered by this plan; certainly no advantage comparable with that obtained by the direct system.

The advantage of storage batteries used in connection with a system of distribution, apart from any increase in the facilities for distribution, is this: It allows the plant to be utilised the entire twenty-four hours of the day, instead of only a part of that period. Now, the plan of Mr. Kennedy certainly does allow a part of the original plant to work the whole time, namely, the engines and boilers; but the dynamos are idle, and the investment has been increased by the purchase of the motor-dynamo, i.e., the machines he proposes to use. Of course, the motor part of the new arrangement can be used to charge the batteries. However, this fact remains, that the capacity of the station is never greater than that of the dynamos that are running. It is a question of economy whether the increased number of dynamos shall be driven by increasing the steam plant or letting the steam plant remain the same, by purchasing a storage battery and motors equal to the additional power required, and wasting afterwards the energy lost in the three conversions necessary, a constant loss of 30 or 40 per cent. (supposing the battery has 80 per cent. efficiency). I think that in most cases it would be preferable to enlarge the steam plant.

I do not know what the arrangement of converters would be in the alternating systems in cases where the wires were necessarily underground. I suppose the primaries and secondaries would be connected as in the overhead lines, a number of the latter to the same circuit. This arrangement is, of course, greatly preferable to using a single converter for each house, since in the latter case the converter would have to be of the maximum capacity needed, while the average energy taken from it for a month would not be more than, say, one-twentieth of this. Using a single circuit for a number of houses partly obviates this, although I might show that the average efficiency of such a system for the twenty-four hours is considerably less than the maximum efficiency of any converter.

To sum up briefly the views given above of the relative values of the alternating and direct systems of distribution, a sufficient portion of the centre cut out, in which space coil referred to is wound. The magnetic circuit is

FIG. 1.—Slattery Generator.

I think that at present the latter has many advantages in densely populated areas, especially if power can be distributed as well as light; while the former is in a better position to distribute light where the population is more scattered. But it is very evident that a combination of the two systems would be vastly better than either alone, in almost any supposable case.

Indeed, when one considers the great advantage that a local lighting company, utilizing any system or any part of a system it might need, would have over companies, as most of them are at present, using only one system and only able to do one kind of work, it encourages us to think that even if no new discoveries were made, but those we have already were properly combined, the cost of domestic lighting by electricity would be less than that of gas. — *Electrical World*.

THE SLATTERY ALTERNATING DYNAMO.

The dynamos herewith illustrated are from designs of Mr. M. Slattery, assisted by Mr. R. Mackie, and constructed by the Fort Wayne Jenney Electric Light Company. According to our American contemporaries, the *Western Electrician* and the *Electrical World*, the Lontin type was selected after competitive trials. The machines have been designed for use with transformers. The machine illustrated is intended to supply current for 1,800 16 c.p. lamps of 50 volts, and has 35 lb. of copper on the armature. The exciter is also shown. The transformer—or as our friends across the Atlantic call it—the converter is constructed as follows:—

The copper wire is wound upon a core consisting of insulated iron plates, rectangular in form, divided centrally, and placed back to back, previously having had

closed around the sides of this coil by the other half of rectangular plate. The induction in this converter is

FIG. 2.—Slattery Exciter.

to a volt per five inches of wire, the ratio of conversion is twenty to one, and there are nearly two pounds of iron

secondary ampere capacity. The working pressure of the system is 1,000 volts at the terminals of the primary coil and 50 volts at the terminals of the secondary coil.

ON THE POSITION AND PROSPECTS OF ELECTRICITY AS APPLIED TO ENGINEERING.*

BY MR. WILLIAM GEIPEL, OF EDINBURGH.

(Concluded from page 187.)

In a colliery at Zankeroda, near Dresden, power is generated above ground by a vertical engine having 10-inch cylinder with 8-inch stroke, which drives a Siemens dynamo. The current is led to the shaft, which is about 60 yards distant, by two bare copper wires, then down the shaft to a depth of 120 fathoms by well insulated conductors, to the L irons, which run along the roof of the wagon way and form the contact rails. The current is picked off these rails by sliding contact pieces fixed to the locomotive, and is led to a switch, which can turn the full current either through the motor or first through reducing resistances and then to the motor. A controlling switch with a seat for the driver is placed at both ends of the locomotive, so that perfect control of the speed and of the starting and stopping of the motor is provided. The length of the line is about 700 yards, and the gauge is 22½ in. A train consists of about 15 tubs, each carrying 10 cwt. of coal; and the locomotive weighs rather over 30 cwt. The journey takes from three to five minutes, the speed varying from five to seven miles per hour. The plant cost a little over £600, including steam engine, dynamo, motor, locomotive car, conductors, and accessories; it has been working successfully since 1882, and was supplied by Messrs. Siemens and Halske, by whom several other mines in Germany have since been similarly furnished. The working cost of hauling 660 tubs, per day of 16 hours, is given by Mr. Rowan, as follows:—

Driver's wages	s. d.
Steam	5 3
Engine-driver at surface	2 3
Lubricating, &c.	3 1½
	1 1½
Interest and depreciation at 15 per cent. per year of 300 working days	11 9
	8 1½
Total working cost per day	18 10½

For the output of 660 tubs or 330 tons per day this amounts to only about three farthings per ton.

Telferage.—The plan of transporting material in skips on overhead wire ropes by means of electricity, introduced under this name by the late Professor Fleeming Jenkin, of Edinburgh, has not so great a field for its use in this country as it may have in less populous regions, because our roads are good, and railways generally near at hand, and we have abundance of water carriage. But in places where material has to be conveyed across hilly districts or over bad roads to the railway or water, it will be found more useful. It has been employed with considerable success for the past two years at Glynde, near Lewes, for transporting clay to the railway over a distance of 1,600 yards, 270 tons are carried weekly at 7½d. per ton. In our larger cities a modification of this plan might advantageously be applied to alleviate the heavy street traffic. In the place of wire ropes, stiff girders might be used, the cars being suspended from wheels running along a rail or rails fixed on the girder. Such a railway would be economically constructed, in comparison at least with the expense of constructing an underground railway; and it would not have any great effect in obstructing the light from the streets, as is the case with elevated railroads for steam locomotives.

A general idea of the present position of electric locomotion in Europe and America is furnished by Table IV., which is an abbreviation of one compiled in May, 1887, by Mr. T. C. Martin, President of the American Institute of Electrical Engineers.

* A paper read before the Institution of Mechanical Engineers, February 2, 1888.

III. ELECTRIC LIGHTING.

Of the four branches of electric engineering dealt with in this paper, electric lighting is the one which, up to the present, has received most attention, called forth the largest outlay of capital, and produced the most beneficial results, if not to so great extent in this as in other countries.

Artificial illumination may be considered in the three aspects of comfort, convenience, and economy.

As regards *comfort*, electric lighting proves itself superior to all other methods of illumination. For indoor lighting, the incandescent light may be utilised and toned down to suit almost any requirement. It may be brought near to any object requiring illumination, without occasioning the least inconvenience from heat or dazzle; or it may be far removed in the ceilings or cornices, without risk of fire or of injury to the decoration. In short, it can be used in any position or for any purposes of illumination for which gas, oil, or candles are available, and for a great many for which they are not available. For outside illumination and large enclosures the arc light gives a brilliancy and cheerfulness altogether unattainable by any reasonable expenditure of gas or oil.

The *convenience* of the electric light has caused it to be highly appreciated, when it is found that by the mere pressing of a button a light is instantly obtained, which can be shaded over in any manner, without danger of setting fire to the fabric forming the shade. It also does away with the constant cleaning of globes or trimming of lamps.

In respect of *economy*, the electric light does not as yet hold out the same decided advantages that it does in the other two respects just considered. In incandescent lighting, the cost of distribution is still heavy, though by increasing the electromotive force and the efficiency of lamps it is being much reduced. In arc lighting, the difficulty of subdividing and of reducing the amount of light given by one arc lamp renders it expensive for general out-door street illumination, as compared with the present low prices of gas and oil. For the lighting of main streets and railway stations, or other places where a concentrated light is required, the arc light is beyond question far cheaper than gas, and its cost per candle power is but a very small fraction of that of gas. As the use of electric lighting extends, the cost of working becomes reduced; installations which four years ago cost 4d. per arc lamp per hour are now costing only 2d. The chief saving has been in the items of carbons and attendance, though the increased efficiency and durability

of the apparatus have also greatly contributed to the reduction: four years ago 11mm. or 0.43in. hard carbons cost 4d. per foot; they can now be obtained for 1½d. per foot, or less than one third.

The following figures supplied by the North British Railway respecting the actual cost of working their electric lights at the Waverley Station, Edinburgh, are interesting as showing how much cheaper it is becoming. The installation is worked by their own staff, and consists now of forty Brush arc lamps, supplied with a current of 10 amperes by a No. 8 Brush dynamo, which is driven by a semi fixed engine.

July to December, 1884, thirty-three arc lamps, 41,884 lamp-hours.

Wages	£165 13 8
Repairs	47 2 6
Carbons	125 15 11
Coal	65 19 11
Oil, stores, &c.	27 15 0
Interest and depreciation at 10 per cent ..	52 2 2

Equal to 2.77 pence per lamp-hour .. £484 9 3

July to December 1886, thirty-nine arc lamps, 55,068 lamp hours.

Wages	£195 17 6
Repairs	78 9 6
Carbons	62 17 3
Coal	23 14 1
Oil, stores, &c.	8 15 2
Interest and depreciation ..	41 10 6

Equal to 1.79 penny per lamp-hour .. £411 4 0

In conjunction with these arc lamps they are running 148 Brush Victoria incandescent lamps, distributed in the refreshment and waiting rooms, and throughout the whole of the suburban station. For these the total number of lamp hours for the half year was 171,251, and the cost was £83 9s. 9d., including all contingencies, equal to 0.12 penny per lamp-hour. There were 113 lamps renewed, which shows an average life per lamp of 1,515 hours.

Local Conditions. The cost of incandescent lighting is especially variable, and affected by the local conditions of the installation. The chief of these are (a) the average number of hours of lighting each lamp, and (b) the average distance of the lamps from the generating station. Where the conditions are favourable, incandescent lighting can already compete with gas, and in a number of installations which have been superintended by the author a large saving is being effected. The following figures, kindly supplied by Messrs. George Jager and Son, show that the yearly cost of lighting their sugar refinery at Leith has been reduced from £317 with gas, to £204 with incandescent lamps:—

Previous average cost of gas lighting per annum ..	£332 13 4
Part of plumber's time	15 0 0
	£347 13 4

Cost of Electric Light, May, 1886, to May, 1887.

Lamp renewals	£46 9 8
Oil, waste, sundries	17 6 0
Coal at 3½ p. per lb. 40 tons at 6s.	12 0 0
Repairs, including men's time attending dynamo	36 5 3
Depreciation at 10 per cent	33 16 0
Gas consumed on Sundays, and when engine is standing	58 4 5
	204 0 4

Saving per annum by electric lighting .. £143 13 0

The average life of the lamps is about 1,400 hours each. The installation consists of 180 Brush Victoria lamps of 17 and 10 candle-power, supplied by a self-regulating Victoria dynamo,

which is driven off the shaft that drives the centrifugal drying machines. The dynamo has been running night and day since it was started two years ago, without failure; it is started on the Monday morning, and runs continuously without stoppage till the following Saturday afternoon.

In the United States there is hardly a city or town of 20,000 inhabitants which has not a central station for arc or incandescent lamps, and many towns of 3,000 to 4,000 are supporting them also. On the Continent large central stations for electric lighting are already in operation in competition with gas; but there the price of gas is generally two or three times what it is in this country.

If the power is to be generated by dynamos and used direct, the cost of distribution on a large scale will probably never be reduced as low as with the existing gas supply; seeing that an efficiency of 95 per cent. can now be obtained with the dynamo, and that steam engines are not likely to be materially improved. It is therefore in the lamps that improvement is to be looked for, by making them with a higher resistance and greater efficiency.

The accompanying Table V., which is an abbreviation of one previously constructed by the author, may be interesting here as showing how the economical sectional area of conductor, and the economical loss of potential vary for the different conditions of amounts lost in interest and depreciation on the conductors, and in horse power wasted in overcoming the resistance of the conductors. The question of conductors is one which must be left to a very great extent at the discretion of the engineer, in view of what are likely to be the requirements of each individual case; but when the conditions have been settled Table V. is useful in showing at a glance the size and cost of the conductor and the ensuing loss of potential.

Transformers.—These are at present receiving a large amount of attention. By their means small high-tension currents of electricity, sent from a distant generating station along a small conductor with a comparatively small percentage of loss, can then be converted into large low-tension currents for the supply of ordinary incandescent lamps. In some arrangements of these transformers the loss in conversion is not more than 5 per cent. Unfortunately the alternating system, which has thus far been adopted, cannot be used with satisfaction for driving motors doing practical work, or for charging storage batteries. The continuous current transformer has certainly the advantage in respect to the supply of power and to the charging of storage batteries; but it is a question whether the disadvantage of having to keep it continually in motion will enable it in town lighting to compete with the alternate-current transformer. The latter is employed in the Grosvenor Gallery central station in London. Some idea of its importance may be formed from the fact that the Westinghouse Co. have already in America over 100,000 lamps at work on this system, although it is not yet so much as two years since they adopted it. Notwithstanding that the use of transformers enables a great saving in copper to be effected, more especially where the lamps are scattered, as in suburban districts, yet it is to be remembered that the insulation of underground conductors forms a very important item in their total cost. The installations already at work are all worked with overhead conductors, with the one exception at Eastbourne; so far as the author is aware, there are no practical data to establish the general applicability of the transformer system for the lighting of large

densely populated towns where underground conductors can be tolerated. The loss owing to induction will be greater with underground conductors however they are installed.

Secondary batteries charged in series by a high-tension current and discharged in parallel circuit, have been tried experimentally, but their practical application is not known as yet. At the same time, now that transformers are coming more used, strenuous efforts are being made to reduce this system of secondary batteries; and if it can be demonstrated to be economical, there can be no doubt that it would have a large field of application. At present, of course, the reduction of risk of the lighting.

It should be borne in mind by electric-light companies that the supply of incandescent lamps is not to be the only source of revenue; but, as already pointed out, the supply of current should be of such a nature that it may be employed for as many purposes as possible. By the use of efficient boilers and engines and by constructing continuous current dynamos, a central station can be so constructed as to be no nuisance whatever, and proper precaution be taken in selecting the site. In towns it will not be necessary to extend the supply very far before a demand will be met with sufficient capacity to supply an engine large enough to be economical. At a certain size the cost of working a steam engine is practically constant for any increase in size; so instead of working from one large central station over a large area, it is found better to work from smaller stations over smaller areas. The cost of attendance will be increased to only a small extent, because one cannot fire more than two boilers; therefore when several boilers are required it is preferable to work them at a central station with another fireman. At Leamington an electric central station is now at work, and the cost of erecting it is about £30,000. The Bradford Corporation recently voted a sum of £15,000 for erecting a central station in their town. Both of these are instances of electric supply, without transformers or secondary batteries.

IV.—ELECTRIC METALLURGY.

One branch of electrical engineering bids fair to become one of the highest interest to engineers. The electrolytic separation of ores on a commercial scale by the electric furnace has but recently been put to the test, in obtaining aluminium from corundum, its richest ore. William Siemens first turned his attention to the matter, but his death occurred before he had perfected his process. It was taken up by Messrs. Cowles, who, with the assistance of Professor Mahery, have devised a furnace, in which by the passage of powerful currents the refractory is successfully reduced. The furnace is built of fire-brick and lined with powdered charcoal to withstand the heat; it is in the form of a box, 5ft. long, 12in. wide and 15in. deep. Current is conducted through the furnace into the ore by means of a number of carbon rods, 1/2 in. diameter and from 2ft. to 3ft. long. The positive and negative carbons are introduced from opposite ends, and meet in the centre. The ore, mixed with charcoal and molten copper, is put in so as completely to fill and cover the carbon. The furnace thus charged is lined with a layer of charcoal and a lid lined with fire-brick without the protection of some such refractory material as charcoal the intense heat causes the firebricks to melt.

When the furnace is ready, the current with an electromotive force of 50 volts is turned on, and is gradually increased up to some thousands of amperes. In a few minutes the metal is melted around the electrodes; and the electrodes are then moved further apart, until the current flows through the entire charge, and the whole is in a molten condition. The corundum becomes gradually reduced, the aluminium combining with the copper, the oxygen with the carbon escapes as carbonic oxide. About five hours suffice to complete the reduction. The furnace is supplied by large Brush dynamos, one of which is specially constructed for the work, and is capable of putting out 300,000 watts, or over 400 electrical h.p. Its weight is nearly 10 tons; 5,424lbs. of copper are wound round the field magnets, while the armature has 825lbs. of

copper on it. Works already in operation at Lockport, U.S., have a capacity of 6,000lbs. per day, and the cost of the aluminium bronze so made is expected to be less than 1s. 8d. per lb., while Mr. Cowles anticipates the price being reduced to 8d. per lb. Works have also been started at Stoke-on-Trent, where a 500 h.p. dynamo has been fixed for generating the current; the potential is 60 volts.

Another electric furnace has been devised by Dr. Kleiner, of Zurich, in which cryolite, a double fluoride of sodium and aluminium, is similarly treated.

When it is remembered that the metal aluminium, in addition to many other good qualities, possesses great strength with only one-third the weight of iron, the importance of obtaining it at a reasonable cost will be readily appreciated; it would undoubtedly cause a great revolution in engineering construction.

The process of welding by electricity, as introduced by Prof. Milha Thomson, is similarly based upon the passage of a powerful current between two electrodes. In this case the two pieces of metal to be welded form the electrodes; they are brought together into close contact, and as soon as the current is sent through the joint its resistance causes intense heat until the weld is perfectly completed. The process is almost instantaneous, and the heating occurs only at the joint; tempered steel can be thus welded without in the least affecting its hardness.

Another plan of electric welding has been introduced at St. Petersburg by Dr. Bernardo, in which the heat necessary for fusion is caused by an arc. The current is conducted to the weld by means of a carbon rod, which is connected by a flexible cable with the positive terminal of a dynamo or battery, while the metal to be welded is connected with the negative terminal. The action of the arc set up by the flow of current from the carbon to the metal may be likened to that of the blow-pipe flame, except that the heating is more intense and sudden, and is therefore more local. The reducing action brought to bear on the metal keeps it clean and unoxidised.

PORTABLE READING LAMP.

Railway travellers not infrequently, when they desire to read, supplement the miserable light usually provided by the companies with lamps and candles, that they may be able to read with some degree of comfort. A few luxurious individuals in the earlier days of electric lighting with accumulators, astonished their fellow travellers by producing a small battery and electric lamp to assist their reading. We remember Mr. W. H. Preece showing such a lamp, which, hanging by a hook from his buttonhole, enabled him

Portable Reading Lamp.

to read while his fellow passengers were muttering anathemas against the oil lamp at the roof of the carriage. The manufacture of such lamps is now forming a recognised branch of Messrs. Woodhouse and Rawson's work, and we herewith illustrate the latest form of such lamps as made by them. As will be seen the lamp is attached to a flexible cord, so as to enable it to be placed in any convenient position. The secondary battery used with this lamp weighs about one and a half pounds, and can be carried in the pocket without difficulty.

CORRESPONDENCE.

THE BRUSH COMPANY'S PROPOSAL.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR, Referring to the notice in your issue of last Saturday anent the proposal of the Anglo-American Brush Company to light a certain area of the City of London, will you kindly allow me to express the feelings of regret with which I learned that the Commissioners of Sewers had again rejected the proposal, owing, apparently, to the rather ungallant interference at the eleventh hour on the part of the Maxim-Weston Company.

For some time past I, as one deeply interested in the introduction of the electric light to Dublin, have been watching with no little anxiety the progress of this proposal, believing that its final acceptance would be the means of imparting a considerable impetus to the electrical industry.

It is much to be regretted that those praiseworthy negotiations (now extending, I believe, over some years) to undertake an interesting and highly important work on legitimate and properly constructed commercial basis should be as it were invaded by the overtures of a practically untried company, whose electrical apparatus has not as yet come very conspicuously before the public.

It would have been very much more conducive to the interests of the electric light generally if Mr. Watts' Company had gracefully stood aside and allowed the work in question to be carried out without obstruction by those who had spent so much time and energy in working the matter up to its present position.

I believe that until some such elaborate scheme as that proposed is in practical operation in London, we in the provinces shall have to wait a long time before our desire to see the new illuminant installed in our streets and houses is gratified.

Therefore it is that I earnestly hope the City Commissioners will reconsider their decision of Tuesday last, and find it to their advantage to come to terms without delay for a grand scheme of electric lighting on sound commercial basis. -Yours, &c.,

ANGELO FAHIE,

Mem. Society Telegraph Engineers and Electricians.
10, Leinster street, Dublin, 28th Feb., 1888.

THE PENTANE STANDARD LAMP.

We have recently had occasion to draw attention to the Pentane standard lamp, devised by Mr. A. Vernon Harcourt, and made by the Woodhouse and Rawson Electric Manufacturing Company.

The excellent work done by this lamp has been shown by Mr. W. T. Doherty in his report upon standards of light to the Metropolitan Board of Works, in which the lamp stood at the head of all the standards tested, and yielded the exceedingly good average of 97 per cent. of tests within 1 per cent. of the mean value, a result we take it never before reached by any standard tested under similar conditions.

We understand that Mr. Harcourt's aim in devising this lamp was to produce a portable and self-contained instrument, dispensing with some of the more bulky apparatus employed in his well-known Pentane standard.

Notwithstanding the excellent results attained by this lamp, Mr. Harcourt believed that he could construct a lamp on a somewhat different principle which would be equally exact and more easily managed. This new form of lamp he exhibited before the Physical Section of the British Association at its meeting in Manchester last year. The new lamp has been put into the hands of the makers of the former lamp, and we append a sketch of it. Instead of burning a mixture of air and pentane, it burns pentane vapour only, and though unprovided with any glass chimney round the flame, burns steadily even when exposed to moderate draughts. At the same time, the important condition that the colour of the flame produced by the direct combustion of the rich pentane vapour should be as white as possible is accomplished, as will be shown by the same apparatus.

It will be seen from our sketch that the lamp takes a form somewhat similar to an ordinary spirit lamp with an additional metal chimney above. The metal chimney, by producing a strong upward draught, serves a twofold purpose—(1) the flame

is kept exceedingly steady, and (2) the temperature of combustion is raised and a whiter light is produced.

It will also be seen that a wick is employed, which would be a distinct disadvantage were it used, as wicks generally are, within the flame or close to the point of combustion of the vapour; but in this case the wick remains at a distance of 2 in. or 3 in. from the point of ignition, and serves only to convey the liquid pentane by capillary action to a part of the tube in which it is volatilised by the warmth conducted downwards from the flame. The wick, it will be observed, is enclosed in a tube, in which it fits comfortably, and which is open at the upper and lower ends. This tube is jacketed by a larger tube, to which it is attached by flat plates. This jacketing serves to produce a steady temperature of the liquid and vapour contained within it, the vapour burning as it is produced at the upper extremity of the tube. These two tubes are further jacketed by another larger one, the upper portion of which is contracted into a smaller tube, which is of the same size as the lower portion of the chimney.

The chimney is itself enlarged in its upper portion, and is attached by two metal bands to the exterior of the larger part of the lower tube. The bands are so shaped as to be at some distance from the flame, and by means of slots cut in their lower

The Pentane Standard Lamp.

portion the chimney of the lamp can be moved up and down within the necessary limits. The lower tube is removable, and is attached to a gallery (solidly fastened to the base of the lamp) by a bayonet joint.

The action of the lamp is as follows:—On removing the lower tube and warming the inner tubes the pentane vapour rises from the opening in the small tube and can there be lighted. On putting on again the large tube with the chimney attached the flame rises above the top of the edge of the lower tube, and by slightly raising the wick the top of it passes into the chimney. In this chimney two narrow slots of 10 mm. high are cut diametrically opposite to each other, so that the tip of the flame may be seen through either of them. When the movable chimney is set at a definite height above the upper edge of the lower tube, and the flame is raised so that the tip is seen to be somewhere between the upper and lower limits of the slots, the central portion of the flame appearing between the upper edge of the lower tube and the lower edge of the chimney gives a definite quantity of light.

It is well known that the light emitted from the centre of a flame is little affected by considerable variations in the height of the flame. With the flame of this lamp Mr. Harcourt has found experimentally what part is of the most constant brightness, and what variation in the height of the flame may be made

without affecting measurably the brightness of this part. The actual position of the interval between the lower tube and the chimney, and the length of the slot opposite to any part of which the tip of the flame may be, are the outcome of these experiments. Mr. Harcourt has found, and his results have been confirmed by subsequent experiments at the maker's factory, that portions of the flame must be selected to give a light of 1 candle or $1\frac{1}{2}$, or $\frac{1}{2}$ a candle, as may be preferred.

Of course, any intermediate values can also be obtained by setting the chimney at various heights above the lower tube, and thus altering the amount of light visible between the upper and lower tubes.

The method for accurately settling the height of the chimney is both ingenious and simple; in fact it forms one of the most attractive features of the lamp. Small gauges of accurate height and exactly fitting the outside diameter of the upper and lower tubes are inserted between them, the chimney is lowered until it rests firmly and securely upon the gauge, it is then screwed tightly to the lower cylinder by means of set screws, and the gauge is withdrawn horizontally, leaving, of course, a distance between the two tubes exactly equal to its height. In the case of the gauge requisite to obtain a half candle it is found necessary to add a small collar upon the lower tube so as to ensure a portion of the flame being used which will remain perfectly constant, even though the height of the flame vary within the prescribed limits. This variation of the height of the flame is found to be exceedingly small after the lamp has been alight for ten minutes or a quarter of an hour and the inner tube has reached a constant temperature, the constancy of which temperature is greatly increased by the method of double jacketing which has been employed.

In order to make the instrument thoroughly accurate, as well as convenient, the inventor has added a base with levelling screws and a simple and efficient method of levelling the lamp, in addition to which he has provided a small piece of glass suitably fixed to reflect the upper portion of the flame visible through the slots, so that its position with regard to the slots may be verified at any time by an observer towards whom the face of the lamp is turned.

The colour of the light is such as to make photometry of ordinary gas lights exceedingly easy; in fact, it is nearly the same as that of the pentane flame, against which no such objections have ever been made on the ground of colour as have been made in the case of the well-known Amyl Acetate lamp.

The lamp has been well tested in exposed positions, and has stood the tests remarkably well, the flame resembling a luminous jetted more nearly than an ordinary flame.

Mr. Harcourt pointed out before the Physical Section of the British Association that, owing to the employment of an upper and lower cut-off, it is impossible to measure distances from any portion of the flame or any part in point of it, so that the law of variation of light according to the inverse square of the distance should exactly hold, but he stated that if distances are measured from a point midway between the axis of the flame and the face of the cut-off, the errors from this cause are perfectly negligible at all distances not less than 10m., and he has ensured this point being easily found by making the metal bands which unite the chimney and lower tube of half the width of the cut-off tube, and by cutting two slots in these bands into which a metal plate can be slipped. The lamp can thus be brought into its true position either by setting the edges of the bands, when the lamp is at the right height, between two plumb lines lying in a plane perpendicular to the photometer bar and passing through its zero, or by direct measurement from the face of the metal plate.

The work done by Mr. Harcourt towards the production of a thoroughly reliable standard of light, and the success which has attended his previous efforts, are sufficient guarantee that the new form of lamp will not only prove a thoroughly reliable instrument, but will be found not less accurate than the previous form invented by him; while the practical experience of the makers of the lamp and their well known accuracy in the production of scientific instruments will ensure the lamp being so made as to bear successfully the test of everyday work.

COMPANIES' MEETINGS.

THE INDIA RUBBER, GUTTA PERCHA, AND TELEGRAPH WORKS COMPANY.

The 24th ordinary general meeting of the shareholders in this Company was held on Tuesday afternoon at the City Terminus Hotel, under the presidency of Mr. S. William Silver.

The report stated that the net profit for the year amounted to £13,174. 10s. Adding £37,955 13s. 5d. brought forward, and deducting £20,800 interest dividend paid in July there remained a disposable balance of £30,330 3s. 5d. The directors, therefore, recommended the distribution of a dividend of 10s. per share, making, with the interest dividend, a total payment for the year of 10 per cent., and leaving £9,530. 3s. 5d. to be carried forward.

The Chairman said it was unnecessary for him to remark that the report presented a state of things very different to the results of many years past. The directors had endeavoured to explain the cause in the report, namely, that the little submarine cable business open to tender had been keenly competed for. The contracts secured by the Company had given inadequate employment to its cable works and steamers during the year, and the expenses of the submarine telegraph engineering staff and plant, though reduced as far as it prudently could be had borne heavily on the gross earnings. Their check to their prosperity, he hoped, would only be temporary. The few orders for submarine cables had told doubly against the results of the year. On the one hand they had not made the same profit in that department as in former years, and certain fixed heavy charges which could not be avoided, if they were to be efficient and ready to execute contracts, had been thrown upon the other branches of their business. It was not too much to expect that electric lighting would shortly come into general use. This branch had occupied a vast amount of anxious attention on the part of the board in order that they might be prepared to meet the demands, however extensive. Their works were, in all respects, in the highest state of efficiency. Under these circumstances the directors had no hesitation in applying some of the profit balance of previous years to the purpose to which it was originally intended—namely, towards equidating dividends.

Mr. Neil Bannatyne seconded the adoption of the report, which, on being put to the meeting, was carried *unanimously*.

TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY (LIMITED).

The 24th ordinary general meeting of this Company was held on Tuesday at the offices, Old Broad Street, Sir Daniel Gooch presiding.

The Chairman, in moving the adoption of the report and the payment of a dividend of £1 16s. a share (making the distribution for the year £2 8s. a share, or 20 per cent.), stated that the Company had laid a considerable length of deep-sea cable, and had done some heavy repairs for the Brazilian, the Anglo-American, and the German Union Telegraph Companies. They had made about 8,000 miles of core wire. They were doing much better than hitherto in their gutta serena business, and he hoped that that would continue. It would not be advisable for him to go into details relative to their business.

Mr. Philip Rawson seconded the motion, which was carried *unanimously*.

The retiring directors and auditors were afterwards re-elected.

SWAN UNITED ELECTRIC LIGHT COMPANY (LIMITED).

The fifth ordinary general meeting of the Swan United Electric Light Company (Limited) was held on Tuesday at the City Terminus Hotel, under the presidency of Mr. J. S. Forbes.

The formal notice of the meeting was read by the acting secretary, Mr. Cover, Major Flood Page being absent on a mission to Berlin in the interests of the Company.

The Chairman, in moving the adoption of the report, congratulated the shareholders on the improvement in the position of the Company, the balance of profit for the year ended September 30 last having been £7,554, compared with £4,768 in the previous year. The total sales for the year had amounted to £27,128, as against £22,000 in the previous year, and the stock on hand at the close of the year was £8,221, against £8,945 a year previously. They held shares to the amount of £208,500 in the Edison and Swan Company, whose business last year resulted in a profit of £16,000, which would have been available for dividend but for the fact that the loss made in previous years had had to be extinguished. That loss, however, was now wiped off. They proposed in their own case to use in a similar manner the profit they had made last year. The loss made by the Company in the previous years had been reduced to £5,000, which it was proposed now to clear off, and they would then start afresh with a balance of £1,720 in favour of the current year. In the case of both companies they were progressing in the sale of the articles they manufactured, and he supposed it was now pretty apparent that, notwithstanding the obstruction thrown in the way of the electric light by legislation and litigation, it was making rapid progress. As the result of the litigation they had succeeded in establishing their claim to the patents in Great Britain. They had had many fights. They had won the contest of Woodhouse and Rawson, which was very important, and on appeal they had won all the points on the Edison and Chubb patent, so that they were, of course, subject to that decision being overruled, which was not likely—the owners of every incandescent lamp in Great Britain. The position abroad was not quite so settled or advantageous. There they were in litigation, and that had dragged on for a long time, and arrived, as far as it had gone, at no conclusion, it was all *inchoate* still. But they were still going on manufacturing and selling lamps. The question was what it was prudent and reasonable to do in that matter. They had tried to do almost what they had done at home in so much advantage, and he would undertake to say that if the Swan and Edison companies had gone on litigating there would have been no such thing as £16,000 profit last year nor any year in which the litigation had continued. By putting their forces together, however, they had made a strong company. He was in hopes that he might be able to announce some sort of treaty or agreement with the foreign companies, embodying and bringing into life that desirable result; but he could not. In Paris they had had communication with the manager of the Edison Company, who were contesting the right of selling in France and in Belgium and in Austria and in Russia, and they had come to something like a basis of arrangement, under which it was proposed they should become partners in the lamp business, just as in the case of the Edison and Swan—that

was to say, put all assets into one pot and divide the profits in proportion. Unfortunately, Mr. Edison's friends seemed to have made some very loose agreements, and the freedom of the French company and their powers to deal were in some measure made difficult by compensation in those agreements. One of the principal litigations was going on in Germany. We heard a great deal about the delays of the law in England; well, it might be some consolation to some to know that in Germany it was something more awful. These patent cases had been on for three years, and as far as he could see they were as far from the decision as they were a long time ago. They were very anxious to get rid of this German litigation, as it was very difficult indeed to get German, with that same energy and untiring love of work, from doing what they did in other places—push over the frontier to sell their wares. That was a reason for making their partners if they could. Major Page was now on his way back from Berlin to tell them the result of his interviews with the parties who pulled the string. If they did succeed in putting things together he had no hesitation in predicting, though he knew predicting was very unsatisfactory, for if one hit the right mark he did not get much credit for it, and if he happened to go wrong everyone abused him—but in this case he would venture to predict a very capital thing for their property. They had then patent for six years, and if they acted with prudence they would, when the protection of the patent ceased, have established a reputation and a connection which would enable the Company to compete with all comers.

Mr. F. R. Leyland (the deputy chairman) seconded the motion. Messrs. J. Verity, Reynolds, Hodges, and others commented upon the position of the Company, and, in reply to the questions,

The Chairman stated that they had obtained protection for their patents as the result of unsuccess litigation, and in regard to the litigation pending with the Anglo-American Brush Company they could give up nothing of the security which they had gained. At the request of the chairman.

Mr. Crisp (the solicitor to the Company) stated that they were proceeding in the litigation with the Brush Company on precisely the same lines as they had proceeded against Messrs. Woodhouse and Rawson, and exactly the same issues were being raised. A second action brought against the Company by the Brush Company was as to their lamp, but they could not discover what possible ground there was for bringing that action.

The motion was then unanimously adopted, and the retiring directors and auditors were subsequently re-elected.

COMPANIES' REPORTS.

ANGLO-AMERICAN BRUSH ELECTRIC LIGHT CORPORATION (LIMITED).

Report of the directors to be presented to the shareholders at the seventh ordinary general meeting of this Company, to be held at the Cannon-street Hotel, London, E.C., on Friday, March 2, 1888, at 12 o'clock:—

During the past year there has been renewed activity in the electrical industry both at home and abroad, and although in the present state of electric lighting the business still calls for sacrifices out of proportion to the rewards it offers, there are indications that it is entering upon a new phase, and the directors have reason to hope that the time is now not distant when the work done by the Corporation will be of a sufficiently profitable character to admit of the regular payment of dividends. The electric light is becoming more and more to be regarded as the light of the near future. Cinemas, hotels, passenger steamers, and war ships are not considered complete unless provided with the electric light, and in the case of theatres lighting by electricity is now recognised as one of the necessary precautions against danger from fire. Municipalities also, whether they own gasworks or not, are showing an increasing inclination to encourage the establishment of central stations for the supply of electricity. The board have, therefore, continued to pursue the policy fully explained in the last report, of developing the business of the Corporation and of anticipating as far as possible the demands which will arise in connection with the carrying out of both public and domestic lighting on a large and commercial scale. With this view patent rights have been secured in connection with the distribution of electric currents of a high electromotive force to be distributed over large areas, and transformed to a low tension for domestic purposes. Considerable progress has been made by the Corporation, in common with others, with this system of distribution, as well as with that by means of accumulators, and the board are now negotiating in several directions for contracts for the establishment of central stations for the supply of electricity. In matters of detail the Corporation have made appreciable advance during the year in the further improvement of their machines and other apparatus, in the better organisation of the business, and in increasing the aggregate amount of their transactions. It is to be regretted, however, that owing to competition and consequent reduction of prices, profits have not increased in anything like the same ratio as the volume of business. Among the satisfactory features of the year's work may be mentioned the lighting of the Royal Jubilee Exhibition at Manchester, by means of nearly 600 arc lamps, to the entire satisfaction of the authorities, and the success which attended this work has materially contributed to the Corporation receiving the contract for lighting the largest part of the forthcoming exhibition at Glasgow, by means of 500 arc lamps. The Corporation also took an important part in the lighting of the American Exhibition in London. They have also carried out a large number of installations in clubs, theatres, on board ship, &c., some of the more interesting being the Lyceum Theatre, Edinburgh; the installations on board the Peninsular and Oriental Company's steamships

"Victoria" and "Britannia," the Hall of the Worshipful Company of Drapers, and the Royal Albert Hall. The long pending negotiations with the Commissioners of Sewers, for the lighting of a part of the City of London have been pushed forward with energy, and although a definite decision has not yet been arrived at the board trust that the matter will speedily be brought to a satisfactory conclusion. It was stated in the last report that the Corporation had acquired the business of the International Electric Company in Austria-Hungary. During the year this business has been energetically developed and there are good indications that it will constitute an important source of revenue to the Corporation. The firm of Krommewitz, Mayer, and Co., in Vienna under which title the Corporation are there trading, have carried out a variety of satisfactory contracts during the year, whilst at Temesvár, in Hungary, where upwards of thirty miles of streets are lighted by electricity, the Corporation have since taking over the installation materially increased the efficiency of the plant, and reduced the expenses of working so that the balance shows on the right side, and the Corporation, having undertaken to supply the light to private consumers, are taking steps to extend the capacity of the works. In the previous report the directors referred to the litigation which was then pending in regard to the infringement by a few manufacturing firms of the patent, held by the Corporation, for compound winding of dynamos. The directors are glad to be able to report that the suit has been antedily settled out of court, Messrs. Crompton and Co., and their colleagues, having accepted licence from the Corporation upon the usual terms, and paid a sum of money in satisfaction of past royalties and legal costs incurred. In connection with this case it became necessary to take the evidence of Mr. C. F. Brush, in America, by commission, and Mr. Percy Sellow, the Corporation's electrician, who was entrusted with the mission, obtained evidence which, as was anticipated, confirmed the position of the Corporation in regard to this matter. Licences to manufacture compound wound machines, under the Corporation's patent, have now been accepted by all the leading dynamo manufacturers in this country, including Messrs. Siemens Bros., Messrs. Crompton and Co., the Edison Swan Company, Messrs. Mather and Platt, Messrs. Elwell Parker, Messrs. Greenwood and Batley, the India Rubber Gutta Percha Company, Messrs. Gosslen and Company, Messrs. Patterson and Cooper, and many others. One firm of manufacturers in Scotland have as yet declined to accept the very moderate terms demanded by the board, and for the protection of the interests of the Corporation the board have lately instituted proceedings with a view to prevent the infringement of their rights. The cross actions with the Edison Swan United Electric Company in which the Corporation were involved at the time of the last report are still pending, but are expected to be heard shortly. This litigation, while exceedingly to be regretted, from its serious character to your interests, is, however, of far graver importance to the Edison-Swan Company, involving as it does the validity of the most important of their incandescent lamp patents, which as would appear from their balance sheet, stand at about £300,000, and upon which they rest their claims for an absolute monopoly of lamp making. The board take this opportunity of placing on record their regret that their efforts to bring about an amicable settlement, consistent with your interests, have failed, and that everything points at present to the necessity of the case being submitted to the final decisions of the courts of law. The board have, however, given their careful consideration to the matter, and have spared no trouble or expense to ensure success in the Law Courts, and the great strength of the evidence they have been able to collect, combined with the high legal and scientific advice by which they are guided enable them to state their full confidence in the result. The Bill introduced last session by Lord Thurlow to amend the Electric Lighting Act of 1882, based as it was in a large measure upon the evidence taken by the Select Committee of the House of Lords in 1885, was very favourably received, and passed by that House, the Prime Minister expressing the opinion that the enterprise should be allowed full scope, that all obstacles which had hitherto impeded it should be removed, and that terms should be offered which experience had shown capitalists would accept. The prospects of carrying the bill through Parliament were therefore very good, had it had proved possible to proceed with it in the House of Commons last Session. The Bill has been, however, reintroduced by your chairman, and there appears a reasonable prospect that it will become law this Session. The capital account shows an increase of £34,939. This is due to carrying into effect the agreement with the International Company, already referred to, which involved the issue of 1,476 fully-paid shares, and to the issue of 1,354 new shares, under the resolution passed at the last meeting giving the directors power to issue new capital for the purpose of developing the business. Owing, however, to the fact that this new issue was not largely responded to at the time, the directors thought it expedient to make a call of £1 per share upon those shares upon which the sum of £3 only had been paid. The increase in the patents, development, and goodwill account of £3,580, is due mainly to the acquisition from the Eastern Electric Light and Power Company in liquidation, of the Brush and Lane Fox patents for the whole of the Indian Empire, exclusive of those for the Presidency of Bombay and the Nizam's dominions, which had already been disposed of by the liquidators. The movement includes also the unexpired balance of the assets and liabilities accounts which appeared in previous balance sheets in connection with the absorption of the Great Western and Brush-Melland Electric Light Companies, and which has been so dealt with in accordance with the principle laid down at the time of taking over these companies, and the payments during the year for upkeep of patents. It will be seen from the balance sheet that there is a marked increase in the amount owing to the Corporation, which evidences the larger volume of business. It will be perceived that despite the larger operations conducted during the year, the general charges show a reduction of about 5 per cent. Several of the economies effected by the directors now appear in the accounts for the first time, amongst these may be mentioned a reduction in comparison with the previous year of nearly

£800 in carriage and freight, owing to an alteration in the classification of electric apparatus, which was conceded by the railway companies in the early part of the year, as the result of representations made by the Corporation. The directors have also been successful in effecting several other and larger economies, which, however, are not yet reflected in the accounts. Among these may be more particularly mentioned the surrender of the lease of the premises at Portpool-lane, and the recent subletting the Borough road works. The item of gross profit, which shows a substantial increase upon last year's figure, reaches the amount of £3,132, being the estimated value of the four-pair shares in the International Company held by the Corporation, and which were relinquished as part consideration for the Austro-Hungarian business. The gross profit strictly due to the current business shows an increase of about 12½ per cent. The directors propose that at the balance of profit £2,500 be added to provision account, and that £2,562 12s. 1d. be carried forward to next account. The directors, following the precedent of numerous other industrial undertakings, have, after mature consideration, decided to adopt the proposal of remunerating the chief officers in proportion to the net profit—decided by the Corporation. The arrangement is that an amount equal to 10 per cent. of the dividend declared shall be set aside as a fund to be divided in proportion to salary, amongst the officers from time to time nominated by the board under special conditions. The board are satisfied that the adoption of this plan will, in view of the appreciation expressed by the staff, have results highly beneficial to the proprietary; and the Board, therefore, cordially recommend it for adoption by the shareholders. Owing to pressure of other engagements, Lord Selsby found it necessary, last spring, to vacate his seat at the board; and, in July last, Major General Waller resigned the position of managing director for that of consulting engineer, adviser, an office which, in view of the immediate prospect of street and private lighting contracts, is one of daily increasing importance to the Corporation. The directors who retire this year, by rotation, are Mr. J. S. Selson and Mr. J. B. Beethwaite, jun., who, being eligible offer themselves for re-election. Messrs Cooper Brothers and Co., the auditors, also retire, and offer themselves for re-election.

PROVISIONAL PATENTS, 1888.

FEBRUARY 17.

- 2430 An improved method and apparatus for effecting the regulation of electrical currents. William Harting Scott and Edward Alexander Paris, 1, Queen Victoria-street, E.C.

FEBRUARY 18.

- 2438 Improvements in the manufacture of illuminating conductors for incandescent electric lamps. Rudolf Langhans, 45, Southampton Buildings, London.
 2449 Improvements in systems of and mechanism for electric railways. Otto Allen, 52, Chancery-lane, London, W.C.
 2450 Improvements in electrical measuring instruments. Walter H. H. H. H., 8, St. Dunstan's-road, West Kensington, London, Middlesex.
 2454 Improvements in the insulation and method of fixing electrical conductors. Walker Moseley, 52, Kimberley-road, Peckham.

FEBRUARY 20.

- 2515 Improvements relating to dynamo-electric generators and motors. James Feaveryear, Gray's Inn Chambers, 20, High Holborn, London, W.C. (Complete Specification).
 2516 A new or improved apparatus or inductometer for measuring the intensity of a magnetic field. Georges Meut, 46, Lincoln's Inn-fields, London, W.C.
 2525 Improvements in arc electric lamps. Charles Richardson, 46, Leopold-street, Weaste, near Manchester.

FEBRUARY 21.

- 2526 Improvements in and relating to incandescent electric lamps. Rankin Kennedy, 96, Buchanan-street, Glasgow.

FEBRUARY 22.

- 2527 Improvements in dynamo machines and electromotors. John Vaughan Sherrin, 77, Chancery-lane, London, W.C.
 2528 Improvements in primary batteries. John Vaughan Sherrin, 77, Chancery-lane, London, W.C.

FEBRUARY 23.

- 2529 Improvements in the construction and method of arrangement of electrical incandescent glow lamps. Arthur French, St. George and Christen Rees Boune, 41, Hatch-lane, E.C.
 2530 Improvements in apparatus for indicating the depth of water in reservoirs or tank by electricity. Luke Berry, Bank Buildings, George-street, Sheffield.
 2531 Improvements in batteries. William Frederick Charles Ward, 1 Laughton Cottages, Melbourne-square, Brixton-road, S.W.
 2532 Improvements in electric lighting. Samuel Miller, 1, Laughton Cottages, Melbourne-square, Brixton-road, S.W.
 2533 Improvements in the construction of sanitary and magnetic mattresses. Edward Parker Dove, Sunbridge Chambers, Bradford, Yorkshire.
 2535 Improved means or apparatus for sounding at sea and elsewhere by electricity. Frederick Hargrave, 38, Chancery-lane, London, W.C. (Complete specification.)

- 2726 Improved means of laying electric light conductors. Alexander Thomas Kinnmont and William Henry Gastrell, 53, Chancery-lane, London.

COMPLETE SPECIFICATIONS ACCEPTED.

FEBRUARY 23, 1887.

- 2819 An improved method of combining and arranging apparatus operating electric lamps for signalling and other purposes. Hermann Nollinger, Strassbourg, Germany.
 2825 Improvements in or applicable to dynamo-electric machines. John Bruce Statter, Norfolk House, Norfolk-street, London, W.C.

MARCH 26, 1887.

- 4549 Improvements in electric incandescent lamps. Albany Featherstonhaugh, Junior, United Service Club, Charles-street, London.

APRIL 7, 1887.

- 5199 Improvements relating to the distribution of electrical energy for purposes of locomotion. William Lowrie and Charles James Hall, 433, Strand, London, W.C.

APRIL 12, 1887.

- 5303 Improvements in dynamo electric machines. Henry Woodcock Ravenshaw, Walter Thomas Goulden, and Alexander Pelham Trotter, 23, Andalus-road, Clapham, London, S.W.

APRIL 15, 1887.

- 5505 Improvements in dynamo electric machines. Henry Woodcock Ravenshaw, Walter Thomas Goulden, and Alexander Pelham Trotter, 23, Andalus-road, Clapham, London, S.W.

APRIL 18, 1887.

- 5637 Electrical controlling apparatus. Alexander Siemens and Edward Frederick Hermann Heinrich Lauekert, 28, Southampton Buildings, Chancery-lane, London, W.C.

APRIL 21, 1887.

- 5833 A combined gas motor engine and dynamo electric machine. Francis William Crossley, 28, Southampton Buildings, Chancery-lane, London, W.C.

- 5835 Improvements in contact makers, especially suitable for connecting wires. Denys Loughton Selley-Higge, 24, Southampton Buildings, London, W.C.

APRIL 27, 1887.

- 6177 Apparatus for adapting electric lamps to the helmets of divers. Albert Marcellus, 28, Southampton Buildings, London, W.C.

JULY 12, 1887.

- 9731 Improvements in or appertaining to ammeters. William Phillips Thompson, 6 Lord-street, Liverpool. (George Westinghouse, Junior, United States.)

OCTOBER 19, 1887.

- 14,204 Improvements in medico-electrical apparatus. John Randolph Hall and Thomas Wilson, 191, Fleet-street, E.C.

JANUARY 29, 1888.

- 1078 Improvements in switches for making and breaking electrical circuits. Sigmond Bergmann and John Thomas Dempster, 23, Southampton Buildings, Middlesex.

CITY NOTES.

Brazilian Submarine Company.—The traffic receipts of the Brazilian Submarine Telegraph Company, Limited, for the week ending February 24th amounted to £4,643.

Western and Brazilian Company.—The traffic receipts of the Western and Brazilian Telegraph Company, Limited, for the week ending February 24 after deducting the bill of the gross receipts payable to the London Platino Brazilian Telegraph Company, were £2,750.

Bournemouth Electric Light and Power Company Limited.—Registered by Deane and Goddard, 3, South square, Gray's Inn, under Table A. Capital £24,000 divided into 800 shares of £5 each. Object: to supply approved centers in the town of Bournemouth and its neighbourhood with electric light and power, and to carry on the business of an electric light and power company in all its branches. The first subscribers are:

	Shares.
F. J. Bright, bookseller and stationer, The Arcade, Bournemouth.	1
J. Denkin, architect, Bournemouth	1
J. J. Allen, house furnisher, The Quadrant, Bournemouth	1
H. Hammond, draper, Bournemouth	1
P. W. G. Nunn, physician and surgeon, Bournemouth	1
C. P. Fippard, cook and confectioner, Bournemouth	1
J. S. Helyer, architect and estate agent, Bournemouth	1
This is the Company referred to in our note on p. 170 of last week's issue.	

Gulcher New Electric Light and Power Company.—This Company is formed for the purchase of the goodwill, patents, plants, materials, stock-in-trade, contracts and other property of the Gulcher Electric Light and Power Company Limited. Owing mainly to losses sustained in the years 1882 and 1883 the Gulcher Company, so the prospectus states, was unable to continue trading advantageously without some kind of reconstruction. Accordingly, with a view to reconstruction, the Company went into voluntary liquidation, and shortly afterwards a committee of investigation was appointed to

report upon its condition and prospects, and to advise as to the course which should be pursued. The capital is £70,000 in 70,000 shares of £1 each, of which 50,000 are 10 per cent. preference shares, and 20,000 are deferred shares. The business is acquired in consideration of a payment of £10,000, and 20,000 deferred shares to the liquidator of the old Company. The present issue is of 25,000 preference shares.

House-to-House Electric Light Supply Company Limited.—Registered by W. Capel Slaughter, 18, Austinfrans, E.C., with a nominal capital of £350,000 in 350 shares, of which 100 shall be founder shares, and the remaining 250,000 shall be ordinary shares. Object: to reconstruct a company recently registered. The first subscribers are:—

	Shares.
Robert Hammond, 117, Bishopsgate-street, E.C.	1
F. W. Bentley, 117, Bishopsgate-street, E.C.	1
J. Whitehead, Hoveat, Crouch End, N.	1
C. G. Haddock, 2, Uxbridge villas, Shooter's hill	1
H. St. John Wentworth, 11, Harrington-road, S.W.	1
W. Capel Slaughter, 18, Austinfrans, E.C.	1

The number of directors shall not be less than three nor more than nine, and the first are George Richardson, Professor R. Bentley, G. H. Godfrey, A. B. Proctor, and R. Hammond. Qualification 100 shares or £500 stock. Remuneration £1,500 per annum, and in addition one-tenth of the annual profits above £7 per cent on the ordinary shares after providing for a reserve fund, but the whole remuneration is not to exceed £3,000 in any year. This is the company whose prospectus we discussed in our leader of last week. We understand the Company has gone to allotment, and one paper says has sent out letters of regret. We shall investigate the amount subscribed and if, as we suspect, the directors have gone to allotment upon a comparatively small amount of the £175,000 first asked for, it is a fact the investing public ought to know.

NOTES.

Germany.—Ten years ago, on the 20th of February, 1878, the first introduction of electric light into industrial establishments took place. It was the firm of Schimmel and Co., of Leipzig, which first of all practically and profitably adopted this new source of light in their workshops.

Silico-carbon Filaments.—According to *Cosmos*, the filaments for the Seel lamps are produced by impregnating silk or woollen thread with a mixture of silicate of soda and gum arabic. The threads are then passed between the two heated cylinders, and, lastly, are carbonised at a high temperature.

The Electric Light in Greece.—M. H. Reo, the new director of the works in connection with the drainage of Lake Copais, in Greece, has just put forward a proposition to utilize the available water power, equivalent to that of 12,000 horses, for the electric lighting of Athens, the Pyrus and Chalcis.

Government and the Telephone.—In the House of Commons on Tuesday, in answer to Mr. Provand, Mr. Jackson said: In reply to the hon. member, I have to state that no scheme for the purchase of the telephone companies' interests is being considered by the Government, nor is any such scheme in contemplation.

Underground Conductors.—The Electrotechnical Society of Berlin has nominated a Committee to consider the question of underground electrical conductors. This Committee is composed of the foremost electricians of Germany, including Messrs. Werner Siemens, Holmholtz, Elasser, Von Miller, Froelich, Golz, &c.

Book Received.—"On a Surf-bound Coast, or Cable Laying in the African Tropics," by Arthur P. Crouch, B.A., Oxon. Sampson Low, Marston and Co. This book forms a portion of a diary kept during a cable expedition down the West Coast of Africa, starting from the English Settlement of Bathurst and terminating at the Portuguese town of St. Paul de Loanda.

Electro-Chemistry. Amongst the recent communications to the *Académie des Sciences*, of Paris, is a note by M. F. Fourmer, entitled, "A method by which may be established the mathematical relations between the physical properties and the chemical properties of simple or compound bodies. Dynamo-electrical law of chemical reactions." The communication may be of special interest to some of our theoretical readers.

Barcelona.—A destructive explosion of gas occurred on the 27th ult. at the Town Hall, where the Queen Regent occupies apartments during the Exhibition. Partitions were thrown down, the heavy *persienne* blinds blown into the square, and the marble balcony was damaged. A gas-man was seriously injured, and eight other persons were more or less hurt by the falling stones. The building is being repaired, and the electric light installed throughout.

Sweden.—The building of the new gigantic steam saw-mill at Korsnas is now rapidly progressing. One of the engines is quite ready, and the other will shortly arrive from Messrs. Bolinder's works at Stockholm, which supply the machinery. Besides these two engines, there will be two more, one for the electric light and the other for the mechanical works. The laying on of the electric light

is now progressing by workmen from Stockholm, and will be completed in a few weeks.

Furness Railway.—On Friday last, about 6 o'clock, flames were observed to break out in the telegraph stores of the Furness Railway Company at Barrow, a building about 150ft. long and built of wood. It was stocked with very valuable stores, and owing to the inflammable nature of much of the material the fire soon had a firm hold of the building. There was a great scarcity of water, and in about an hour and a half the entire building was destroyed, the damage amounting to many thousands of pounds.

Street Railways. An affidavit has been filed referring to the Bentley-Knight electric system, in connection with a petition from the North and East River Railway Company of New York, to the Legislature of that State, by Mr. J. J. Houghton, the effect being that, in his opinion, and in view of the successful operations of the said Bentley-Knight system in other places, and, after a careful consideration of the plans, certified by the engineers of the road and submitted to him, Mr. Houghton is certain that successful operation of such a system cannot be called in question.

Bismuth.—In the course of experiments on the heat conductivity of bismuth when placed in a magnetic field, it was observed by A. Righi that the isothermic lines were rotated in a direction opposite to that of the magnetising current when a rectangular strip of the metal was placed with its planes normal to the line of force. The phenomenon is analogous to that observed by Hall, namely, the rotation of the equipotential lines when a magnet acts on a current flowing along a thin strip of metal, and may explain the thermomagnetic currents recently discovered by Ettingshausen.

Melbourne.—The forthcoming International Exhibition to be held at Melbourne will be lighted by means of 800 Brush arc lamps of 2,000 nom. c.p. and about 3,000 incandescence lamps of 17 c.p., operated by 37 No. 7L Brush dynamos and 7 E2 Victoria machines. The Anglo-American Brush Electric Light Corporation have just contracted with the Australasian Brush Electric Light Power and Storage Company for the supply of the whole of the dynamo machinery and arc lamps required for this extensive installation, and have undertaken to ship all the apparatus by the end of the first week in May.

Journal of the Society.—The new number of the *Journal of the Society*, just issued, contains the President's Inaugural Address, the conclusion of the discussion upon Mr. Cockburn's paper on "Safety Fuses," as well as an abstract of the papers which have appeared in Foreign Publications, and a list of the important articles which have also appeared in such publications. The discussion which arose out of the paper on "Fuses" is of itself of importance, and should be studied by all electric light engineers, because it contains the experience of those who have been engaged in the industry from its commencement.

Electrolysis.—When an electric current passes from a solution of certain metallic salts with the atmosphere of gas or vapour immediately above such solution, an electrolytic separation of the metal takes place at the surface of the liquid. M. J. Gubkin has recently described (*Ann. Phys. Chem.*) certain apparatus by means of which this is made evident, and in which a partial vacuum may be produced above the liquid. Silver and platinum are found to separate out in films which float on the surface; whilst zinc, in contact with air, oxidises as it separates; the white

flakes of zinc oxide gradually falling to the bottom of the liquid.

House of Commons.—Mr. Hobhouse on Monday asked the First Commissioner whether he proposed to take any steps this Session for establishing electric communication between the library and the House, so as to inform members occupied in the library of the progress of debate and the names of speakers. In reply, Mr. Plunket said the question of the establishment of electrical communication between the House and the library and other parts of the building has been considered, but there has not been up to the present time sufficient unanimity of feeling among hon. members in favour of the proposal to justify him in going on with it.

The Telephone in Hospitals. We take the following from a "society paper":—"There is a talk of applying telephones to the infectious wards of the French hospitals, so as to enable the sick people isolated in their contagious sufferings, to have the comfort of hearing their relatives' voices, without any risk of conveying infection by an interview. It certainly is a very humane idea, and would not, one would think, be a very costly one to carry out. We commend it to the benevolence of some English millionaire who wants to do a good deed, or wishes to perpetuate the memory of some beloved relative by a benefit to his suffering fellow creatures.

The Optical Projection Stenotelegraph. This apparatus, devised by M. Lambotin, has been laid before the committee of consultation for posts and telegraphs recently constituted by M. Coulon, the director-general of this department in France. It allows of the optical production, by means of an electric or oxyhydrogen lamp, of stenographic signs or characters, which may be photographed upon a screen at the distant station in communication, or which may simply be read from station to station by means of a telescope. It is proposed to utilise this system more especially in time of war and during the night, when the services of the carrier pigeon are not available.

Arc Carbons.—According to the *Revue Scientifique*, the most advantageous thickness of carbon for arc lamps, taking the currents specified, is given in the following table:—

Current in amperes.	Diameter of carbon in millimeters.	Current in amperes.	Diameter of carbon in millimeters.
2 to 3	2	15 to 24	13
3 to 5	4	16 to 25	14
4 to 6	5	25 to 30	15
7 to 10	7	30 to 45	17
10 to 11	9	35 to 60	18
11 to 15	10	40 to 80	20
12 to 16	11	50 to 120	25
13 to 20	12	80 to 180	30

For heavy currents, our contemporary recommends bundles of carbon rods of 4mm. diameter or fluted carbon rods.

"L'Electrotherapie." This is the title of a new periodical devoted to the subject of medical electricity and published in Paris (11, Rue de Magador). It is edited by Dr. Leon Danion, who has secured the scientific collaboration of Messrs. Bernhardt, of Berlin; Onimus, of Paris; De Watteville, of London; Vizioli, of Naples; Weiss, of Vienna; and Virgilio-Mathado, of Lisbon. Amongst the articles contained in its first issue is one by M. H. Revel, in which the necessity for the accurate galvanic measurement of currents applied to various portions of the system is duly insisted upon. It would certainly be most interesting, here in London, to be

informed of the value in milliamperes of the currents evolved from appliances largely advertised by "eminent" medical electricians.

The Electric Light in Paris.—The electric lighting firms in Paris have something equivalent to our Electric Lighting Act of 1882 to contend with, in the shape of the *Cahier de Charges*, or Conditions of Contract, elaborated by the Committee of the Municipal Council of Paris. Great dissatisfaction has been expressed in many quarters in relation to the obligations and restraints imposed upon concessionaires. The most recent expression of this feeling is to be found in a circular, which has been addressed to their clients by Messrs. Ch. Mildé, Son and Co., who were to have carried into effect the electric illumination of the Monceau quarter, by means of a central station distributing the light to the Parc Monceau, Malesherbes, les Ternes, and the Champs Elysées. The circular simply states that, in view of the onerous conditions imposed by the Municipal Council, the firm has relinquished the idea of establishing the central station in question.

Selenium.—Amongst the selenium cells constructed by S. Kalischer, three were found to differ from the rest in their behaviour on exposure to light; the resistance rapidly increasing after undergoing a momentary decrease, and the cell returning to its normal condition only after remaining for some time in the dark. Copper and copper-brass electrodes were used in these three cells. The conclusion has been drawn from the above phenomena that the cells in question contain a hitherto unknown modification of selenium, the conductivity of which decreases, instead of increases, under the action of light. It may be, however, that the effects are dependent upon the nature of the electrodes, as the remaining cells have electrodes of zinc, copper-zinc, or copper-platinum. Experiments have been made by M. Bellati and S. Luasana upon the influence of light upon the heat-conductivity of selenium. They found the value 1:1.1 as the ratio of the heat conductivities without and with exposure to light.

Electric Lighting in Spain. The *Gas World* is hard upon the Concessionaire who proposes to obtain motor power for electrical purposes from the falls of Manzanares. It says:—"Electric lighting in Madrid is very much hampered by the local regulations which practically prevent steam engines being set up within the city. A concession has been given to M. Gabriel Faura for bringing in electricity from the falls of Manzanares, some 14 miles from Madrid. This river is very variable; in winter it flows in a wide and turbulent stream, and the bridge across it at Madrid is a very long structure. In summer, on the other hand, it is nearly dry, and the disproportion between the large bridge and the meagre stream is so great and apparent that it has given rise to a local proverb. When a person appears to make a greater display than his resources would presumably permit, he is said to be like the Manzanares: 'he has sold the river to pay for the bridge.' It remains to be seen how far such a stream is suitable for electric lighting."

The Elements not Patentable.—In arguing the Bell telephone case before the Commissioner of Patents the other day, says the *Scientific American*, Robert G. Ingersoll, one of the counsel, closed his argument with the following pertinent remarks, which it will be well for all inventors to remember. The conclusions are sound and as applicable in other cases as the one on which the learned counsel made the application:—"I do not believe any man can patent the idea of sending speech by electricity. He can patent de-

vices by which that can be done, but he cannot get a patent on the lightning. A man can patent a water-wheel, but he cannot patent the water, or say to the water you cannot turn any other wheel but mine. A man can patent a windmill, but not the wind; and any man who can make a better mill may use the same wind, because we do not get our entire stock of wind from the Patent Office or from the attorneys on the other side. Wind is the free gift of all politicians; and, looking at the attorneys of the Bell people, without wind where would your case be?"

The Caloriphone.—This name has been given to a very wonderful but not altogether novel—nor, as yet, perfected—apparatus, devised by a young French soldier and *lucide des sciences*, M. Léon de Pontois. The object is to obtain telephonic communications without the use of a conducting wire; the distance between the communicating stations being comparatively very great. The inventor, in fact, speaks of an apparatus, weighing 10.5 kilos, and costing from 80f. to 100f., which will communicate through a distance of ten French leagues. The system by which this result—which for the present we are loath to accept with a grain of salt—may be obtained is summarised as follows:—The conversion into luminous undulations of the vibrations impressed by the voice to a telephonic plate; the reception of these undulations by an optical apparatus of great power, their conversion into calorific undulations; and their reaction upon a substance, such as selenium, which, by transmitting them to a telephonic receiver, transforms them into articulate words. According to the *Revue Internationale*, experiments with this apparatus are immediately to be made between Mont Valerien and other forts in the vicinity of Paris.

Rather Inconvenient.—A curious thing occurred last Thursday evening, when we had quite severe lightning, says the Orlando, Fla., *Record*. One of our surveyors was out in the woods surveying, and on the approach of the storm took shelter under a large tree, leaving his compass on the jack staff, some two or three hundred yards away. During the storm a tree very near the compass was struck by lightning, and, strange to relate, the effect upon the compass was to reverse it so as to make the north point of the needle change position and point south. The gentleman not knowing that fact, when he went back to the compass took a sight and started, as he supposed, for home. After walking eight or ten miles, going north, as the compass indicated, he, away in the night, came to the house of an old settler, who, upon inquiry, told him where he was and how far from Orlando, and the proper direction, which, of course, was exactly opposite to that indicated by the compass. After becoming satisfied something was wrong with the compass, and that the settler was right, he retraced his steps, and arrived at home tired, wet, and cross. This is the second instance we have known of the needle of a compass being affected by lightning so as to become reversed.

Improvement in the Edison Lamp.—We translate the following from our excellent little contemporary, the *Bulletin International de l'Electricité*. The paragraph refers to the Edison lamps employed for public lighting:— "In the case of public installations, when all the lamps are simultaneously rendered incandescent or extinguished, the arrangement in series offers numerous advantages from the point of view of simplicity of construction and working. A somewhat serious difficulty, however, arises from the fact that any lamp accidentally breaking down must be auto-

matically thrown out of circuit, in order to prevent the extinction of all the lamps. After numerous experiments, the Edison Company of New York has arrived at a very simple device, which appears to give very successful results. A third platinum wire is passed into the glass bulb, between two bunches of the filament. In the stem of the lamp this platinum wire is connected to a very fine iron wire, by which a spring is maintained in a condition of tension. When the filament of a lamp becomes broken, a voltaic arc becomes formed between the positive extremity of the carbon on the one hand, and the negative extremity and platinum wire on the other hand. The current thus traversing the latter suffices to fuse the iron wire, allows the spring to act, and by this means establishes a contact which cuts the lamp out of circuit. By means of this contrivance, the series arrangement may be adopted without any inconvenience."

The Schanschloff Battery.—On the occasion of the opening of the new line of the London and South-Western Railway to Bournemouth, a new feature in railway travelling was introduced in the form of electric lighting by the use of the ordinary roof lamps. A number of these ordinary lamps belonging to the company had been altered into electric lamps by the use of the Schanschloff primary battery, several of the saloon carriages being so lighted. Several forms were adopted, some lamps being fed from the outside by simply moving a plug; but by far the most interesting ones were lighted or extinguished from the inside by simply pulling a chain. These latter were much appreciated, as being very convenient for sudden lighting for tunnels, or extinguishing easily in case sleep might be required, to say nothing of the saving in cost. The light was very clear and white, and remained remarkably constant and steady throughout the whole trip. Great interest was manifested in the light, and we believe several railway directors expressed their intention of recommending its adoption. We learn that similar lamps are being made for other companies. During the trip Mr. Schanschloff also exhibited the guards' hand lamps, and other of the Schanschloff electric appliances, which are attracting great attention in the railway world. These are practical experiments, and by the results obtained, after a moderate interval devoted to such trials, we shall be better able to judge the value of such a method of illuminating railway carriages.

New Edison Lamps.—The march of improvement in the Edison system, says the *Electrical Review* of New York, has resulted in the perfecting of a new type of lamps of much greater economy than those which have been made by them so many years. Broadly stated, the new High Economy lamp of the Edison Company carries with it a saving of one-third the power required for the former style, and whereas the company formerly guaranteed 8 to 16 candle-power lamps to the mechanical horse-power, they now guarantee 12 for an expenditure of the same power, or 15 to the electrical horse-power. The old plants of the company are being rapidly fitted with the new lamp, which, of course, marks in the mind of the user of the plant the fact that electric lighting is making substantial progress. The new 16 candle-power Edison lamps range from 90 to 125 volts, and require only $3\frac{1}{3}$ watts per candle-power. The 100 candle lamp is also one of the new type of lamps, and ranges from 90 to 125 volts, requiring an energy of $3\frac{1}{2}$ watts per candle power. Always specially constructed for use with storage batteries of comparatively low E.M.F. (60 volts) and re-

quires only $2\frac{1}{2}$ watts per candle power. The Edison Company is now also making a series of lamps of similar economy for battery purposes, but running from 20 to 40 volts and from 10 to 32 candle-power. Another lamp is used in connection with Edison central stations. It is of high resistance, and requires 150 volts to bring it to incandescence. When therefore it is run at 110 volts it gives but a dim light, and this is what is desired, the lamp being intended for a night lamp, in bed rooms and other places where only a small amount of light is desired.

Motors and Mining.—The *Western Electrician* (Chicago), in calling attention to two installations for mining purposes, says:—"In one instance the contract calls for the delivery of 2,000 horse-power, three miles from the primary source—a water-power—on an island, and the circuit will cross an arm of the sea 4,000ft. wide. In the other instance a circuit of 18 miles will be erected and power distributed at fourteen different points along the circuit. Our contemporary has repeatedly called attention to the mining regions of the west as a most promising field for the electric motor. In many places the price of fuel is prohibitive, especially where the only method of transportation is on a burro's or mule's back up steep mountains. If the method were reversed and, Mahomet-mountain like, the ore were transported to power for crushing, again the cost would be prohibitive; but if power could be applied directly at the mine without too great cost, then the cost for transportation would lie in taking the net products of the ore crusher to market. In the mining districts it frequently happens that water power in abundance is found, but at too great a distance from the place where the application of power is desired to be utilisable. For instance, one miner had this problem; a mine that promised to yield ore of high grade but located on a mountain side six miles away from power; no method of transportation, save on mules' backs, and with that method of transportation a cost of production that forbade development of the mine. The miner is now investigating the electric motor. The two installations described are important in that they will bring the electric motor prominently before the mining interests of the country, and show what achievements can be attained by the electrician, and they are important and interesting to electricians on account of the problems involved and the methods of solution adopted." We have no doubt that such firms as Messrs. Immisch and Co., who make a speciality of motors, have not overlooked the immense field for the use of their motors the mining world represents, and will not allow America—if English energy and enterprise go for aught—to monopolise this work.

Electric Lighting in France.—The work in connection with the central station at Tours is progressing satisfactorily. A few of the shops in the *rue Nationale*, along which the mains have been laid, are still lighted with gas; but the cafes, the circus, the theatre, and all the largest establishments in the quarter employ the electric light. The number of lamps actually working is about 2,000, and will shortly be augmented to 3,500. The current is supplied by three alternating-current dynamos. In regard to the financial results of the enterprise, which were at first unsatisfactory, in consequence of the low charge of 3½fr. per 16-candle lamp per month made to subscribers—the lighting being from dusk till 12.30 a.m.—these have been made remunerative by the adoption of a tariff of 5 centimes per lamp hour; the minimum period of

lighting being four hours per lamp per day. We regret to say that the central station at Vierzon, inaugurated a few months ago, has not been a financial success—experience in this as in other directions having in some cases to be paid for. The experience gained by the *Société d'éclairage électrique de Vierzon* will no doubt, however, be valuable to other companies undertaking similar work. At Lyon the question as to the general adoption of electric lighting remains undecided; the Municipal Council desiring, apparently, to stimulate to the utmost a competition resulting in a lowering of the price of the gas supplied to this city. — The administration of the *Chem de fer du Nord* is actively carrying out the electric lighting of the stations on its lines. That at Pontoise is shortly to be supplied with 90 incandescence and two arc lamps; the motive power available will be 35 horse power. The station at Busigny will have a 70 horse power motor, working 130 incandescence and 12 arc lamps; whilst that at St. Ouen l'Aumône will be the occasion for a transport of energy through a distance of 1,200 metres with the object of charging the accumulators in connection with the incandescence lamps for lighting the offices. Lastly, the quantity of light at the station of Plaine St. Denis is to be more than doubled; the number of arc lamps becoming 17, and the incandescence lamps 100. The Kresic arc lamps are to be employed in these installations.

Cost of Electric Lighting.—Our contemporary, *Industries*, commenting in its last issue upon the Maxim-Weston offer to light the City, says:—"This company offered to erect a central station generating plant, and eight hundred small arcs throughout the City, for the modest sum of £15,000, and to work the plant for an annual charge of £3,875. The lamps were to be 450 n.e.p., and to be kept alight from sunset to sunrise, that is, roughly speaking, for 4,300 hours per annum. The lamps are presumably the Watt lamps, about which a great deal has been written in the daily press, and nothing at all has transpired in the scientific journals. To judge by the reticence observed both in the matter of the dynamo and the lamp, the inventor seems to prefer the verdict of the non-scientific newspaper reporter to that of a skilled electrician when he submits his invention for inspection. We have, therefore, no means of knowing anything about the merits or otherwise of the Watt lamp; but assuming this small lamp to be as efficient as an ordinary 10 ampere lamp—an assumption which is by far too favourable—each lamp would require 225 volt-amperes; and allowing a loss of 25 volt-amperes for the leads and regulating devices, we find that each kilo-watt generated at the station would maintain four of these lamps alight. For the 800 lamps, the total capacity of the generating station would have to be about 200 kilo-watts, and the yearly output 860,000 Board of Trade units, which, calculated at the low figure of 6½d., represents a charge for current alone of £2,325, to say nothing of the cost of carbons, which will probably amount to one-fifth of a penny per hour per lamp, representing an additional outlay of £2,800 per annum. This does not include the cost for trimming lamps nor outdoor supervision, which must necessarily be high where a large number of small lamps is employed. From our figures it is obvious that the Maxim-Weston Company must have made some mistake or other in estimating the annual working expenses, which they will find out to their cost, and perhaps to that of the City also, if they obtain the contract on these lines. It is obviously

the advantage of any community to get contractors to do for them at a loss, for in such cases the public is to be badly served. We may therefore also dismiss the Maxim-Weston proposal as impracticable on account of the reasons, and the question remains whether any system in any shape or form would be an improvement on the present system of gas lighting."

City Lighting.—A good deal of correspondence on this subject has appeared in various papers, but two in the *City Press* of the 3rd inst. put the matter as it is to users. One correspondent, signing himself "on Street" protests that the arrangement between the Gas Company and the Corporation was foolish, and that, over too long a period, the advantages were not obtained, the system of lighting contrary to every principle of science, the system should not be used but incandescent for streets, and the evidence as to price was inconclusive.

The concluding sentences of the letter are as follows:—"When a company appears on the scene prepared to contract, under penalties, to supply lights of this kind, at the same price, light for light as gas, then we can think of it. When it will be cheaper than gas, without too many chains round corners, then we may adopt it. Till then I venture to assert that while glow-lamp lighting is the best position of light for interiors, no proof has yet been shown that there is any advantage whatever in electricity for the purpose of street illumination." The signed "A. L. F." treats the subject from a business point of view, and from his letter we cull the following facts:—"Take Wood street as an example. In this thoroughfare there are eighteen gas lamps of 16 to 20 candle-power, at a cost of £65, where the business cannot be less than 25 millions sterling yearly. The extra cost to light this thoroughfare properly would be at £100 per annum. This is really, where such a volume of business is transacted, not worth contention, and the difficulty about lighting one portion of the street brilliantly at the cost of the other parts not so easily overcome by charging the district (on a previous agreement) an extra rate. Failing the adoption of this suggestion, a guarantee fund could be raised every morning in Wood street from the proprietors of the leading warehouses. Buyers from all parts of the world visit this locality to make purchases, and any one can see and the depressing effect a miserably-lighted street in the afternoon has on the spirits of a buyer, having a full bill of commissions in his pocket. Its dreary, miserable, lighted thoroughfare would, under the circumstances, give new to this country the impression that they had come to the wrong market, and that they ought to defer their purchases until they visit Paris or Berlin. It is well known that there are so few accidents or robberies after dark on such a narrow crowded thoroughfare so badly lighted, that no doubt due in a great measure to the excellent management of the City Police organisation. If the City Council could make a few inquiries within their own boundaries of the merchants where gas has in a great measure been superseded by the electric light, they would find sufficient evidence to warrant their deciding in its favour. Apart from this, if they were to refer to doctors who practise as specialists for the wholesale houses, they would find ample proofs of many young men's health having been ruined through having to work day after day underground in the bad atmospheres mainly caused by gas. From a practical point of view, a brilliantly-lighted city is likely

to give a fresh impetus to trade, and have a marked beneficial influence on those occupied in it."

A Private Installation.—Mr. George Vaughan Fowler, a member of the firm of Fowler, Lancaster and Company, electrical engineers, of Birmingham, has carried into effect a complete installation of the electric light at his residence, the "Old House," near Warwick. The following details of this installation have been given by the local press. The engine shed contains a Spiels petroleum engine used to drive the dynamo. The engine at Mr. Fowler's house is nominally two horse-power, but will work up to about three and a quarter horse-power. It requires only a few feet of room, and is attended to by a boy of 15. This engine drives, by an endless belt, made of small links of leather combining great strength with flexibility, one of the Fowler Lancaster shunt-wound three unit dynamos. These dynamos embody the latest improvements, are free from "sparking at the brushes," are very durable, and are besides of extremely neat appearance. The current, generated in the dynamo, is led, by the ordinary cables, to a neighbouring outhouse, to a set of "E.P.S. accumulators," and this forms one of the most interesting features of the installation. The accumulators in Mr. Fowler's installation hold sufficient current to supply his lamps for three winter days' consumption. There is thus no need to run the engine at night time when the light is required, or on Sundays. In the day time the accumulators can be charged, and by always keeping a day's supply in hand a temporary breakdown in the machinery would not involve the house in total darkness. By a simple arrangement, the connection between the dynamo and the accumulators would then be automatically cut off. From the accumulators the current is led into the house through a switchboard placed on the landing. Upon the board there are several switches. One is a main switch, which cuts off the current from the house and stabling altogether, and the several minor switches cut off or supply the current to various quarters of the house and premises. Each lamp, in its turn, has a small switch to itself in the apartment where it burns, so that any of the lights can be on or off at will. The house fittings are of a most handsome character. There is nothing in connection with the light that is unsightly, nothing in fact that is not artistic, and that does not add to rather than detract from the appearance of the room in which it is placed. There are altogether in the house 54 lamps, of 50 volts, varying from 8 to 50 candle-power. The lamps at the gateway are of 50 candle-power each. They are enclosed in globes of glass slightly frosted on the inside, which are placed at the top of thin iron supports resting on the gateposts. Their light is most efficient, and it is possible to read small print over 30 yards away. The stables are also fitted with the electric light. The main point which determines whether such a luxurious system can become general in large country residences is that of the cost. It is said the cost of this installation is above double the cost of oil. That the system gives advantages which no other kind of lighting can approach cannot be denied. It follows, therefore, as a matter of course, that as soon as the system becomes known many gentlemen will adopt it at their homes. No damage is done to paint or ceilings in putting in an installation, and the leads are more easily laid than gas piping. There is no danger of fire. Should an electrical short-circuit take place by accident, ill consequences would be averted by the fuses with which each switch is provided.

PRACTICAL ELECTRICAL UNITS.

BY W. B. ESSON.

(Continued from page 153.)

One instrument for measuring differences of potential deserves special notice, inasmuch as its action depends on neither of the properties of the current already mentioned. I refer to the Cardew voltmeter, in which the expansion of a platinum-silver wire, caused by heating due to the passage of the current, indicates the difference of potential at the ends of the wire. Since heat is employed to give the indications, the instrument can be kept on continuously without introducing temperature errors, which in the case of other instruments become fatal to accuracy. It can also be employed to measure alternating differences of potential, since there is no lag due to self induction.

For the measurement of electric power several instruments, termed *wattmeters*, have been devised, but they have not come into general use. Generally, a wattmeter consists of a pair of coils: one a fixed coil of coarse wire through which the whole current in the circuit flows, the other a movable coil of fine wire, to the terminals of which is applied the difference of potential between the two points between which it is desired to measure the power. The mutual attraction between the coils measures the watts, and the movable coil may either be moved against a controlling force, and caused to take up a position depending upon the power being measured, or the tendency to movement may be balanced by the torque of a spring, or by weights in a scale pan. The former is an indicating and the latter a zero instrument. The wattmeter, though it tells us the product of current and difference of potential, does not tell us anything regarding the magnitude of the two factors. If the current were 20 amperes and the difference of potential 100 volts, the wattmeter would show 2,000 watts, but it would give the same indication were the amperes 200 and the volts 10. The instrument is therefore unsuitable for general use, for by multiplying together the indications of an ammeter and voltmeter we can always obtain the power being used in the circuit, and the exact way in which the current and difference of potential are related.

To obtain the resistance between two points of a circuit in which a current is flowing, we have simply to divide the difference of potentials in volts between those two points by the current flowing in amperes, i.e., divide the reading of the voltmeter by the reading of the ammeter. But in cases where there is no current flowing we have recourse to the Wheatstone's bridge method, which need not be enlarged upon now as it has been already fully described in this journal by Mr. Thomas Gray.* In his article will also be found a description of the precautions which have to be adopted in employing the method, and the degree of accuracy which can be obtained by it.

15. Mechanical Measurement.—For the measurement of mechanical quantities there has been devised a number of instruments to which the generic title of dynamometer has been given. A dynamometer in the usual acceptance of the term is therefore any instrument which measures mechanical work or power. Beginning at the prime mover, we have for the measurement of the power given out, the steam engine indicator, which draws to scale the diagram of work done in the cylinder for each stroke of the engine.† On the exterior of a drum, which has a reciprocating rotary movement given to it by means of a cord attached to the crosshead, is fastened a piece of paper on which is drawn, by a pencil moving parallel to the axis of rotation, the indicator diagram. The pencil holder is connected by levers to a piston moving in a small cylinder which is in communication with the cylinder of the engine. The pressure of the steam on the underside of the piston is counteracted by a spring, and the height to which the pencil rises indicates the steam pressure at any moment. The stroke of the engine in feet being represented by the movement of the drum about its axis, and the pressure of steam in pounds

per square inch by the compression of the spring, a diagram is drawn by the instrument, the area of which gives the work done in foot pounds per stroke on each square inch of piston area. Of course it will be understood that the pressure in the cylinder is varying from moment to moment throughout the stroke, and that to obtain the mean pressure we must take diagrams from both ends of the cylinder. The indicator pipes are generally attached so that, by turning a cock, the diagrams from both ends can be drawn on the same paper and without disturbing the indicator. Having obtained from the diagram the mean pressure, we multiply this by the area of the piston in square inches, by the stroke in feet, and by the number of strokes per minute, when the product divided by 33,000 gives the indicated horse-power. From what has been already said the reader will perceive that the indicated horse-power is an average rate of doing work. The pressure in the cylinder and the velocity of the piston are continually varying throughout the stroke, so that the rate of performing work is sometimes considerably above the indicated horse-power, at other times considerably below it. What the above product really gives is the average pressure into the average velocity, and therefore the average rate.

But the engineer is not satisfied with knowing only the power of the engine driving his dynamo. It is doubtless very satisfactory for him to know that for a certain indicated horse-power he gets a certain amount of light, that from his dynamo he gets in electrical energy 70 per cent. or so of the energy given by the engine; but there is here a total loss of 30 per cent., and he wants, as far as possible, to find out where the losses occur. Really, if it were not too much trouble, he might set up apparatus which would enable him by careful measurement to write out a balance-sheet with all the credits truly set forth, and balancing the amount of power debited at the engine. But usually he has to be contented with a balance-sheet somewhat imperfect, though nevertheless useful. A description of the apparatus employed to make the necessary measurements, having this end in view, we shall reserve for another article.

(To be continued.)

SCHLESINGER ELECTRIC LOCOMOTIVE MOTOR.

The work of Mr. W. M. Schlesinger, the electrician of the Union Electric Company, in the field of electric traction has attracted considerable attention, and we are glad to be able to give further descriptions and illustrations of his work.

The motor represented by Figs. 1 and 2 is capable of giving 35 h.p., and is designed especially for locomotives having to haul heavy loads. It is 27½ in. broad, 43½ in. long, and 22 in. high, and weighs, with countershaft and gear, 1,500 lb. The armature is of the Siemens drum type, 9½ in. in diameter, and has a core 10½ in. long. The wires are wound within troughs fastened to the core of the armature, and are thus prevented from being displaced either to one side or to the other by the pull exerted by the magnets on them. This pull with a motor varies from one side to the other as the direction the motor runs in is altered, and tends not only to loosen the wires, but also, by causing them to move, gradually to destroy the insulation.

The armature makes about 1,000 revolutions, the countershaft about 400. The bearings of the latter are part of the same frame in which the two armature bearings are cast. This keeps the two shafts parallel under all conditions, and insures an easy running of the gears, even with the most trying alteration in the load. After six months' running the teeth of the pinion showed a wear of $\frac{1}{8}$ of an inch, i.e., about $\frac{1}{16}$ of an inch on each side of the tooth.

The 32 part commutator is placed outside the bearings, and is constructed in such a manner that it can be taken off and replaced by a new one within an hour and a half, it being unnecessary to disturb any of the other parts of the machine, or to make any electrical connection otherwise than to solder the wires into grooves in the commutator

* *Electrical Engineer*, February 10, 1888, page 128.

† As the various methods of measurement can only be described here in a general way, the reader is referred to a useful little book on "Indicator Diagrams," by Prof. Kennedy's chief assistant, in the press, and about to be published by Messrs. Charles and Co.

here. As all these wires are so arranged that they can be placed in no other groove than the one to which they belong, it requires no electrical knowledge or training to accomplish this. The great advantage of this method can be seen when comparing the time and work required for the exchange of an old commutator for a new one on

months in the Lykens Valley Coal Company's mine at Lykens, Pa., hauling daily about 500 tons gross weight over a road 6,300ft. long. This load is gradually being increased, and it is expected to haul about 1,000 to 1,300 tons gross weight daily. Some of the work this motor has accomplished was to haul a train weighing about 150

FIG. 1.—The Schlesinger Motor.

this motor, with that required for a motor having the commutator inside the bearings. With the latter it is not only necessary to take the motor more or less apart, but also to remove it from the truck or car to which it is attached; furthermore, in most cases (nearly always when the Siemens type of armature is employed) the front cap has to be removed, and it requires a thoroughly trained work-

man, consisting of 31 cars, and 380ft. long, round two curves, the one having a radius of 20ft., and the other 30ft., and the distance between them being 180ft. This same train had afterwards to be started while standing partly on a level and partly (100ft.) on an up-grade of 15in. in 100ft. The average number of cars hauled by this motor in one trip varies between 10 and 20, these cars being loaded

FIG. 2. The Schlesinger Motor.

man or electrician to replace the wires. All this requires from 8 to 24 hours' time and about 3 men. Having the commutator outside the bearing, it has the further advantage of allowing at all times an easy inspection of it and the brushes, and facilitates the proper setting or adjusting of the latter.

One of these motors has been running for the last six

months in the Lykens Valley Coal Company's mine at Lykens, Pa., hauling daily about 500 tons gross weight over a road 6,300ft. long. This load is gradually being increased, and it is expected to haul about 1,000 to 1,300 tons gross weight daily. Some of the work this motor has accomplished was to haul a train weighing about 150 tons, consisting of 31 cars, and 380ft. long, round two curves, the one having a radius of 20ft., and the other 30ft., and the distance between them being 180ft. This same train had afterwards to be started while standing partly on a level and partly (100ft.) on an up-grade of 15in. in 100ft. The average number of cars hauled by this motor in one trip varies between 10 and 20, these cars being loaded partly with coal and partly with rock or slate. A second motor of the same type will in a short time be in operation in another part of the mine, where it will have to haul daily 300 loaded cars, representing a gross weight of about 1,500 tons, and 300 empty cars weighing about 450 tons, so that the total load of this motor will be nearly 2,000 tons.

ARTISTIC ELECTRIC LIGHTING.*

BY H. SWAN, A.S.T.E.

There are two quite distinct and different ways of considering an installation of electric light. One, that is familiar to us, concerning volts and amperes, wires, switches and fuses, dynamos and engines, is that of the electrical engineer; the other is that of the consumer, his wife, and the interior decorator, and concerns itself primarily with the artistic nature of the fittings, the brilliancy, softness, and disposition of the lamp, and its general suitability and convenience for actual use.

I should like to point out strongly, to those who are electrical engineers, three things to consider with respect to electric lighting.

The first is, that the public—the men who want electric light in their homes—do not care one jot, as a rule, how the electricity is produced; battery, dynamo, storage, or central station, is all one, except as it affects the cost. They do not care for dynamos: do not care to know about them, do not want to have them, and are only too glad to do without them—only put up with them when they desire the light and cannot get it without some generator. What they want primarily is *pure light*, which, when they have it, shall be as beautiful and convenient and dependable as possible.

The second thing I would insist upon is the influence of the ladies—the wives. Some men there are who will arrange, order, and see carried out their own ideas imperiously; but I am sure I only state a fact when I say that generally it is only after long and serious deliberation with the wife that such changes as replacing gas or oil by electricity are undertaken. This being so, clearly the right end to begin at in order to forward the spread of electric lighting will be the careful consideration and greater attention to actual beauty of form and arrangement of the fittings as appealing to the ladies, and to the spread of a greater knowledge of its varieties, conveniences, and beauties for household use.

Thirdly. That although it might appear that handsome effects can only be obtained by paying heavily for them, yet in reality it is not so. It stands, of course, to reason that large and handsome electroliers cost more than plain ones, but I wish to insist upon the fact that for a given cost a place may be fitted to look in every way artistic, well lighted, and even luxuriously fitted, with exactly the same expense as, done in another way, would have given a plain, mean, and cheap appearance; and simply by the expenditure of a little taste, judgment, and knowledge, as well as of wires and fittings.

Each house, and each room in the house, should be considered separately, hall, club, shop, or dwelling—as an architect considers it in planning it—and not only so, but each room should be treated according to its own requirements both as to disposition and amount of light, and to harmony of decoration.

Nothing is easier than to sling a number of plain cord pendants all over a building—pleasant and easy work for the electrical engineer—and nothing has a more unfinished, mean, and irritating effect, however good the light, to anyone with the slightest artistic feeling for decoration. Think also that the light itself is decorative, the shape of the globe is lovely, the light soft and sweet—itsself “a thing of beauty and a joy for ever.” There are houses I could name where the incandescent lamps are themselves quite one of the prettiest features of the room. Yet others again have been fitted with no sense of fitness—thick lumping holders, shades of all degrees of crude, inharmonious colours, switches looking more like a small model of a dynamo or some such piece of engineering than a piece of household furniture fitted for a lady's fingers.

The fittings should be chosen, then, light and elegant and in keeping with the character of their surroundings and their duties. There should be no heavy wrought bracket like a cantilever girder, to hold nothing heavier than a 2in. globe of blown glass and a vacuum; but the flexible cord itself should be made use of as far as possible, either alone or decorated with fancy knobs or ornaments (which can be

easily and cheaply made of twisted wire or spun brass balls). One of the best effects is with brackets of various designs in twisted brass or light wrought iron work—the flexible cord passing openly in and out, through vulcanite “nipples” where going through the metal, and suspending the lamp at the end.

With the incandescent lamp, unlike gas, nothing has to be considered (after the cost) except the effect required to be obtained, no restrictions of placing for fear of burning or soiling or heating the things in juxtaposition, tables, walls, ceilings, tapestry, pictures—all alike are safe—only the best effect is to be considered. This we are not used to from constant use of gas, and sometimes very beautiful and unconventional effects can be obtained by remembering it. Let us now consider the different effects required in a good dwelling house, and how best to obtain them. I will give one or two hints of how the lighting has been fitted in some of the houses of the West End.

Drawing Room. The principal room is generally the drawing room—here is most light required and most variety advisable. The electroliers should be open as far as possible, not too much shaded, that is, should aim at dispersion, not concentration of light. In a small room, a 5 lamp electrolier is often used, with one or two additional standards or brackets at either end. If a long room, it is advisable to have two of them. In a low room, a series of brackets round the walls is preferable; in a high one, the electrolier takes off the sense of emptiness. A device often used in good houses when gas has not been used, but candles were preferred, is to adapt the candle sconces, if handsome, with flexibles from behind the wall, and holders fitted with a brass plate in which are two small holes. Into this can be fitted the wires of a semi-circular silk shade, made on a wire frame fitted with white silk, or coloured, or ornamented, according to taste. The shades are fitted to stop the light striking the eyes, and reflect it on to the wall, thus giving a soft general light over all. It is a good thing in all rooms of any pretension to run round behind the skirting a “lead and return” with sockets for movable attachments at intervals round the room, and to have one or two table standards with shades that can then be moved about as desired and connected by long flexible cords.

Switches. The switches in the movable fittings should be in the fittings themselves. The switches to sconces on the wall should be near them, and just at the height of the hand. It is a nuisance to have to search around in unlikely corners for the switch, but for an electrolier it is often best to place the switch just inside the door, as it opens the hand finds it at once, occasionally it is placed just outside, and can be turned on before entering.

Candlesticks to be adapted are better not drilled, but a plate should be screwed or driven in the top, and the holder with attached flexible cord fastened to that. The holder should be neat, not straggling or mechanical looking, and is better electro-plated to match the candlestick. Silk shades, movable, can be adapted to candlesticks as well as to sconces.

Dining Room.—Unlike the drawing room, the light here want concentration. The dining table is the centre of attraction, and a bright light on the table, shaded from the eyes, and comparative dimness at the corners of the room, is the desideratum. One or two lamps, in sconces, brackets, or standards, of 10 candle power, can be placed at the sideboards; but the chief lighting for the dining room should be enclosed in a large hanging dome or silk covered shade spreading over the table, and capable of being moved up and down by a counter weight arrangement. For an ordinary table, five 16 candle power lights is a good number; and it is well to arrange them with two switches, one to control two, and one to control the other three. You can then have two, three, or (with both on) five lamps on, at will. In some cases it is required to travel back and forwards as well as up and down. This can be arranged with a spring wheel (to coil up the slack), fixed in the ceiling between the rafters, if desired.

Hall.—For this you want a good general light. A 32 candle power lamp is advisable “to welcome the coming, speed the parting guest.” A good effect is got by having a lantern made of upright rows of round clear glass rods arranged cylindrically with the lamp in the centre. Lamps

* Paper read at the City and Guilds of London Institute Old Students' Meeting.

in the ceiling with cut glass are often used, and also brackets.

Picture Galleries. These must be considered in two different ways. Do you want a good general light all over, or do you wish a bright picture line and a dim centre? The latter is best for public galleries or show rooms of a large size, and can be obtained by hanging a series of 30 or 50 candle power lamps at distances of 6ft. to 10ft. all round the gallery not far from the wall and just above the pictures, the lamps to be encircled with hammered shells of metal whitened inside (not brightened or plated, which casts strange lights). These shells should be suspended by cords, and tilted slightly at an incline to throw the light on the picture line.

For a general light, electrolights should be used, or a series of cord pendants, but in either case all the light should be stopped as much as possible from going upwards to the ceiling, and be reflected on the walls. They may be obscured for softness.

For a large picture gallery, 50 or 100 candle power lamps are useful. A useful addition to a picture gallery is a large reflector on a standard with wheels for throwing light on particular pictures with a 50 candle power lamp. Single noted pictures are often fitted with their own bracket coming out of the top of the frame and shielded with a shell to throw the light wholly on the picture: it should be whitened or gilded inside.

Bed Rooms.—There are so many different arrangements for hall rooms that it is difficult to say which is best; but for large and high rooms use lamps of higher candle power. Remember too, that while much light is required, it is wanted soft and harmonious and not too brilliant. Ladies wish to appear at their best, and a too glaring light is not good. An American furnisher has gained society's applause and gratitude by modifying the too brilliant glare of the incandescent filament into delightful softness and harmoniousness by a very simple means. He envelopes each bulb in a small bag fitted with an elastic round its top and made of straw-coloured silk.

Bed Rooms.—The lamps should be available for giving a good light for dressing by, and should be susceptible of being turned on or off from the bed. A table lamp for reading is also required sometimes.

Stair and Passages should have plain fittings, as a rule, and opal reflectors.

Kitchen and Basement—Opal reflectors often get broken here, tinned and enamelled iron ones are more advisable. A moveable one on a handle near the fireplace, for introducing into pots, to look at the contents, is very useful to the cook.

Counterweight Pendants.—These are very useful and convenient, and can be used in all sizes and designs, plain or ornamental. Care should be taken that the wheel, or run

the case by varying the candle-power of the lamps to suit the different situations. It is too often the case that 16 c. p. lamps are used all round, and floods of light are expended in corners, passages, lavatories, &c., which had much better have had 10's, or even 5's; more light being reserved for where it could be better employed. A 10 candle-power lamp in a double-faced lantern, let into the wall between two lavatories, is often quite enough, and will sometimes efficiently replace two 15's, or four times the power.

Thirty, 50, and 100 candle power can much more often be used with advantage than is yet usual. Four 50's give an effect equal to, or better, in a large space, than that of twelve 15 candle power; and, of course, at a cost for renewal of 20s. instead of 60s. One 100 candle-power lamp will light a large shop window splendidly at a very moderate first cost, but it is necessary to have specially made holders for these high candle-power lamps, and a solder contact is better than the contact of two round wires (which, remember, is mathematically no more than a point) to carry 4 or 5 amperes of current.

THE BENTLEY-KNIGHT TRAMWAY SYSTEM.

In our issue of February 24th we described the Bentley Knight motor and gearing for driving tramcars. We now

FIG. 1.—Contact Plough.

illustrate the details of construction of the conduits, conductors, and contact pieces, or, as they are called, contact ploughs. Fig. 1 shows the contact plough making contact with

ning surface, where the double flexible touches on, is not metal, but vulcanite or ivory—or faced with some insulating material; the hook which keeps the cords together should also be of insulating material.

Cut Glass.—Cut glass has a very fine effect, but is costly, and requires constant cleaning to keep brilliant.

Lamps.—A great deal more can be done than is usually

the conductors in the conduit, the section of which is shown in Fig. 2, and the method of connection in Fig. 3. The conduit, Figs. 2 and 3, in which the conductors are carried is an important part of the system. In construction the iron yokes are set upon the ties, and they are strengthened by webs let into the ties themselves. The conductors are hung from a continuous insulating lining. The lowest

point of the yokes is less than 15 inches below the surface of the street, while the extreme width of the conduit is 26 inches. The contact ploughs used to make connections between the motors and conductors are provided with swivel joints allowing them to easily take curves, and they are mounted on guides which give them full play across the whole width of the car. These ploughs (Fig. 1) can be inserted or withdrawn from the fin. slot at any point along the line, and nothing can by any accident be left behind to obstruct the progress of succeeding cars. The constant potential system is adopted. The dynamos are compound wound, and Prof. Thomson's new method of winding is adopted, in which the main circuit field coils closely surround the armature and oppose the tendency to a change in the line of commutation under varying loads. The efficiency of the motor is said to be 90 per cent. The current strength usually employed is about seven amperes, but the motor is said to be able to stand 30 amperes for any length of time.

Regulation of speed is effected by resistance in the motor circuit. Both motor and brakes are governed by the ordinary brake handle. A separate lever is used for reversing at the end of the run. Toothed gearing is used throughout for the transmission of power from the motor to the axle. The construction and equipment of 10 miles of tram line per horse-power costs 201,000dols., for electric power 462,000dols., for cable 803,000dols., while the annual running expenses in the three cases are respectively 107,040dols., 51,891dols., and 101,210dols.

If this estimate is even approximately correct, it shows that the annual cost of running tram lines by electricity is far less than by horse-power or cable traction, and although the initial expense for electric construction and equipment is greater than that for horse power, the annual expense of electric traction is less than half that of horse traction. The engineers state that in all cases the maximum prices have been charged against the electric system and minimum prices against horses and cables. Of course it is extremely difficult to verify such statements, and there is no doubt that the cost must differ very considerably in different places.

INSULATION AND INSTALLATION OF WIRES AND CONSTRUCTION OF PLANT.

BY PROF. ELIOT THOMSON.*

I have been requested to present my views on the above subject, and having recklessly allowed myself, in spite of the many other demands upon my time, to accept the chairmanship of your committee on the same subject, I have felt it my duty to at least say enough to provoke a general discussion and interchange of views between others who may have given more special study to the matters in hand. My endeavour, therefore, will not be to arbitrarily lay down any rules, but rather to point out directions in which information may be gained and improvements made.

The subject is certainly very extensive in its scope, and could not be dealt with except in a very superficial way in the time at our command, and meanwhile I feel constrained to state that I make no claim to the possession of any of the qualifications which would be requisite for thorough work on the subject.

In the installation of an electric light or power plant we first of all find that the conditions vary very widely. Its size, location, the distances covered, or length of circuits, and the climatic effects met with, need to be considered.

Then, again, the nature of the plant itself, whether arc light, direct incandescent, alternating system with transformers or converters, &c., governs to a large extent the conditions of the installation of the wires and of the plant itself. We may, of course, find in a single station or installation representations of these and other characters of plant, such as medium potential circuits for power transmission alone.

Three or four years ago we should have been required only to take into account simple cases of high potential for arc circuits and low potential direct currents for incandescent multiple arc circuits, but the range now covered may be considered to be from any potential above 50 volts up to several thousands and any current strength from about one ampere up to several thousand amperes.

In considering the proper insulation and installing of wires for conveying these potentials and currents, we are required to still further extend our field of view and divide them into aerial

or overhead wires or conductors and underground systems, and each of these taken in connection with the conductors for indoor distribution to the lamps, motors, or other energy users. We have thus outlined the field which should be covered in dealing with a subject such as we have before us. Insulation and installation of wires and construction of plant would furnish us a subject material to fill a many paged volume, and not by any means exhaust it. May such a work soon be forthcoming.

Concerning the relative merits of overhead conductors and underground conductors, it is pretty generally agreed that, except for expense and the difficulties of insulation and connections from the mains, the underground system would be preferable, as avoiding unsightliness and liability of interference either by leakage, inductions, or contacts with other overhead wires. Now, to preserve insulation of the lines conveying high potentials, which potentials cannot be avoided if distance is to be covered without conductors of such size as to have a prohibitive cost, is a vital question. It may well be conceded that when the potentials are very low, say 100 to 200 volts, the difficulties of insulation are very slight as compared with those of the use of two or three thousand volts.

It is a notable fact that so far as concerns the placing of overhead wires, particularly the wires of telegraph, telephone, and other such systems, and in some cases of electric light wires, extreme disregard of systems or orderly direction for such wires is the cause of much of the unsightly appearance presented by them, and much of the liability to get out of order. The tendency also has been to use very light and easily broken wires for telephonic work, such as may at any time come down upon the necessarily stronger electric light wires, strength being synonymous with efficiency in these latter.

It is thought that there is need of some rules or enactments to render impossible the mazes of telegraph, telephone, private wires, fire alarms, live wires, dead wires, and electric light wires (which for our purposes may be considered very live wires), such as may be seen in many of our large cities.

Should the wires of all kinds be laid or hung in orderly bundles having a definite direction, and only changing that direction by definite angles, such as right angles, in accordance with a pre-arranged system, I think that much of the objection now existing to the placing of overhead conductors could be eliminated. Add to this a requirement increasing the durability and tenacity demanded for telephone and telegraph wires and their supports, and the dangers of leaks and grounds would in a large measure be removed.

Many trials have been made, and considerable progress has resulted therefrom, in the direction of securing an insulating covering for electric wires as may adapt them to the use of high potentials without leakage and prevent contacts forming by abrasion with other wires. This appears to be one of the most difficult problems in electric engineering. The problem is not so much to find a first-class insulating substance for wire covering, but to find combined therewith, or to combine therewith, the qualities of indefinite durability where exposed to the weather, and great toughness and power of resisting cutting or abrasion. For overhead work not only is an excellent insulator capable of withstanding very high potentials without leakage or rupture required, but such property must be retained along with the mechanical properties of hardness and toughness for indefinite periods. Besides, the cost must not be too great.

To what extent any quality of insulated wire or insulating material for outdoor use fulfils this requirement is a matter which it is difficult, indeed, to determine fully, particularly as a test for durability must necessarily require a long time to complete. Indeed, it would seem that our best guide must be the experience gained in the use of different wires on a large scale under different climatic conditions and without extremes of heat and cold more or less great.

Aside from the insulation given to the wire by its covering, considered purely as an insulator, most stress must be laid upon the requirement of resistance to mechanical friction or abrasion, as tending to give immunity from grounds by contact with other wires or with tree branches, roofs, corners, &c. Toughness and elasticity of the insulation are hence seen to be qualities of high importance.

Whether such mechanical tests as will represent the conditions of actual practice in the use of the wire in relation to abrasion and percussion, bending, &c., which may break through the coating of insulation, can be devised and applied to test wires is somewhat doubtful, though without doubt much information may be obtained in the pursuance of such an object.

The retention of the toughness and elasticity for a reasonable period is of course demanded, and it is this retention which in otherwise excellent coverings is often absent, the effect of exposure being to render the materials brittle and porous.

It has often been proposed to make tests for the insulation resistance of the coverings of certain lengths of any wire, taken as examples representing an average for such wires, under potentials somewhat exceeding that existing under actual use or practice, and so to determine the in-

* Read by Mr. E. W. Rice, junr., before the Electric Light Convention.

insulating capabilities of different coverings; but it is my opinion that while such tests are certainly useful and important and, in the case of underground wires and cables, indispensable, yet, for overhead work, since most of the length of the wire is exposed to air only, which is a practically perfect insulator, and since the chance of a leakage from the lines arises most from imperfectly insulating supports and from accidental contacts with other wires or surfaces, additional tests would in any case be required to determine the suitability of an insulator for overhead lines. In this connection it may be stated that during thunderstorms overhead wires are subjected to violent inductive effects, giving rise oftentimes to the momentary charging of the lines with potentials very far in excess of the potentials of any dynamo, and capable of breaking through the wire covering, where it may be near or touch a metal object or wet surface. This breaking through may give rise to a weak spot which will be followed by the dynamo current itself, if of high potential, and if at the same time other conditions be favourable to a diversion of current.

When overhead wires or pole lines are required to pass through and between branches of trees, a condition not infrequent in many of our towns and cities, considerable difficulty may be found in preserving the insulation of the line, the covering of which is apt to be rubbed off by the tree branches swaying in the wind. Fastening insulators to the branches for support and attachment of the wires is an uncertain remedy, on account of the swaying of the trees taking place in different directions not transverse to the line of wire, so that the wire is strained or detached from its support along with the insulator by the violence of the actions. Many and ingenious are the devices which the over zealous lineman makes use of to suddenly, or gradually and mysteriously lop off the offending limb, when the case is exceptionally critical, and permission for the amputation of the offending member cannot be obtained from the conservative citizen whose sidewalk supports the obstacle to the lineman's ambitions.

It is also customary to thicken the insulation of the wire at such places as are threatened by abrasion by winding on it a scale band of tough and adhesive tape, such as can now be found in the market. If neatly and thoroughly done, the insulation of the wire may thus often be preserved under decidedly adverse conditions.

It must be admitted that the insulation of a high potential circuit can never be too good, and that therefore any measure which may tend to its improvement and preservation is a double advantage, for not only are the dangers of grounds and leaks lessened, but the power of the current to do useful work is assisted. A considerable leakage from a high potential circuit means, indeed, a loss of power or efficiency of the system. For instance, the loss of one-half an ampere of current at a potential of 1,500 volts, would represent about one horse power of current energy lost, costing more than a horse power at the dynamo pulley to supply such a leak. This latter consideration is of especial importance in dealing with the lines feeding transformers with alternating currents at high potentials.

With 1,000 volts in the primary circuit it is readily seen that a badly constructed or leaky line might easily cause the loss of a considerable percentage of current, such as would reduce the economy of the system, more particularly when running under light loads, at which time it is desirable to secure and to keep the best possible efficiency.

When wires or cables are to be laid underground their resistance to abrasion is of importance only when they require to be drawn into conduits or sections of conduits, but when once placed intact they are not necessarily further subject to mechanical injury, as they are generally surrounded by protective casings or tubes.

The total exclusion of moisture and the possession by the wire coverings of a high insulation resistance are requisites of great importance in such work. The difficulties are with low potentials comparatively easy to provide against, but in the case of wires at high electric potentials or pressures, such as are light or alternating current primary lines, such difficulties are much exaggerated.

The least excess of moisture, such as may occur by flaws in the insulation, may result in the production of a bad ground, or a slight leak, due to some original defect, may so improve itself by the passage of current as to become a bad fault or a complete connection to earth. It would seem best in all cases not to place reliance upon the integrity and perfection of but a single insulating coating or covering for the wire, but to give it, say, three coatings successively applied, and which are, in a measure, independent coverings, all of them impervious to moisture and good insulators. If composed of different materials, the peculiar liabilities to defect of one such coating may possibly be compensated by other qualities in another coating, so that there may be small chance of superposed defects in all coatings alike.

Let but the insulating capacity of each layer or coating be amply good to withstand the potential used, and it is difficult to conceive how trouble could arise from leaks due to defective portions of the covering. First cost is, however, a barrier to the perfection of underground systems, to save which cost less effective and cheaper structures are often given the place which should be occupied by the more perfect and more costly.

It is important that, in cases in which overhead wires or wires above ground are connected with underground lines, efficient means for carrying inductive discharges to earth be provided, such as is secured by the use of proper lightning arresters, for faults may otherwise be produced in the best underground system of conductors due to static inductive discharges existing during thunderstorms, at the moments of lightning discharge. These discharges are in overhead lines oftentimes quite vigorous, and capable of puncturing moderate thicknesses of insulation. They are not to be confounded with actual passages of lightning strokes to the lines, which, of course, have an infinitely greater capacity for mischief.

The preservation of the insulation of inside wiring is not difficult where the potentials used are low, nor is it difficult with due exercise of care and skill in the running of the wires and the selection of suitable courses for them to take, to install simple series lines, such as those for arc lights, which shall be practically exempt from leakage, unless abraded and brought into contact with conducting objects or moist surfaces involving leak to earth. Unfortunately, owing to lack of skill and judgment and haste in installing, much of the wiring done is not as well done as it should be for the best results.

Distribution of current to groups of incandescent lights upon arc light or other high potential lines should always be undertaken with great care, and it is thought that such work should only be undertaken when exceptionally favourable conditions for avoiding accidental leakages exist, especially should the potential of the line at the dynamo exceed 1,500 volts, or an amount which would sustain thirty arc lamps in series. One of the important elements of safety in such installations is simplicity and ease of inspection of the wiring, and no concealed wires should be used in them.

Concerning the wires which are suitable for indoor work and particularly for high potentials, the endeavour has been to combine moisture proof and fire resisting, or rather incombustible, materials in the covering. The difficulty has been to find moisture resisting substances which would not carry fire, and fire resisting or incombustible material which would not carry or absorb moisture. The two properties seem in most cases incompatible. The tendency now is to surround the wire with a first covering of moisture proof material of the nature of rubber, bitumen, resins, &c., and outside of this to place a second layer which will not carry fire.

For house to house and general incandescent lighting, where the distances from the station are not too great, the direct low potential systems possess most of the advantages, the difficulties of leakage from the defective insulation being of course at a minimum, but where the distances are so great as to make the required outlay for copper in the conductors practically prohibit the extension of the system, a transformer or converter system, if of good design and economy, may be made to yield excellent results. In such cases the high potential primary wires need not enter the building, or when they do may be suitably protected, the house or inside lines being of such low potentials as to be run with ordinary precautions as to leakage. However, the integrity of the system would be changed should a connection or leak form between the primary and secondary wires of the transformer, thus connecting the local or house line with the high potential outside mains. Such a connection might easily exist unsuspected, and would be a constant source of menace or possible danger, not discoverable by the mere tests for grounds as applied to the primary line at the station.

The expedient of securely grounding the secondary or local lines was devised by me to overcome this difficulty. It insures immunity from the risks arising out of possible leaks from the primary lines to the house lines, because such leaks are at once detected by the ordinary tests for grounds.

The consideration of the subject of what appliances are the best for the detection and location of leaks or faults in the insulation of conductors when they exist, and whether the ordinary crude methods are adapted to all cases by such detection would prolong the present paper much beyond its intended limits, and it will have secured its object if it opens up an opportunity or gives occasion for a free discussion and the interchange of experience and ideas upon the general subject forming its title.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS—STUDENTS' MEETING.

A meeting of the students took place on Thursday, the 1st inst., Mr W. M. Morley being chairman.

Mr. W. E. Haynes opened a discussion upon Mr. Cockburn's paper on "Safety fuses, &c.," describing several improvements, one of which is to replace the leaden pellet an essential part of Mr. Cockburn's fuse, by a small spring. A duplex cut out was also mentioned, devised by himself and his brother, in which a second fuse is thrown into circuit after some definite time has elapsed, useful in cases of accidental or designed short circuits lasting only for a short time.

Messrs. Lamb, Hume, Rance, and Morley continued the discussion. A vote of thanks to the chairman terminated the proceedings.

THE ELECTRICAL ENGINEER.

Published every Friday.

Editorial and Publishing Offices:
139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their intentions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BROS., 139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** for a series can be arranged on application.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at **THREE WORDS for ONE PENNY**, with a **MINIMUM** charge of **SIXPENCE**.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations, or it can, if preferred, be supplied direct from the Office, on the following terms:—

	3 months.	6 months.	12 months.
United Kingdom	3s. 3d.	6s. 6d.	12s. 6d.
Within the Postal Union 4s. 4d.		8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BROS., 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 we gave a Portrait of E. GRAVES, Esq., President of the Society of Telegraph Engineers, and stated our intention of giving a series of Portraits of eminent Electricians of the century. In fulfilment of our promise we have already issued a Portrait of W. H. WOLLASTON, M.D., F.R.S., who was in his scientific prime at the beginning of the century. This will be followed by SIR HUMPHREY DAVY, F.R.S., whose fame as an electrician is still more prominent than that of WOLLASTON. Portraits of Past Presidents of the Society are in preparation, and we hope soon to have ready that of PROF. D. E. HUGHES, F.R.S.

PRICES AND COMPETITION.

In our article of last week on transformers or accumulators, was a sentence which deserves much more consideration than it is likely to get while embedded in the middle of that article. The sentence we refer to reads as follows:—"It is an open secret that profits on the manufacture of dynamos have of late declined almost to the vanishing point." The fact is too true, and may be accounted for in various ways. This result is partly a legacy left by the electric light boom of 1881-3. Companies were then floated, which, in their eagerness to get some sort of a business, ran down prices so that it became impossible for respectable firms to follow and live. Then, when the pinch came, workmanship was sacrificed to cheapness; purchasers subsequently finding out that their so-called bargains were of a costly kind. The amount paid for attempted repairs was greater than the first cost of the dynamo, and this after a short wear, so that in a good many instances the machine descended into the scrap heap, and its original place knew it no more. The bankruptcy court and the auctioneer—admirable institutions as they are in their way—have much to answer for in the lowering of prices. Another incident in the downward march has been caused by quotations made to get on the Government list. It may be that in some cases the work so obtained was profitable; but we are inclined to think the profits in many cases were of the most intangible character, and we are quite sure the result on the whole has not been satisfactory.

The number of firms entering into the trade and dealing with electrical apparatus is largely increasing; and it is with a view to their interests, as well as in the interests of the older firms, that we have ventured to discuss this subject. The industry is rapidly extending. With energy and caution, new firms may spring up and be successful. Too great a rush however into the business must be deplored, as must every attempt of new firms to obtain business by unduly lowering the catalogue prices. Undoubtedly, if the profits obtained in any industry are abnormally large, it is in the interests of the general body politic that more capital and more competition be embarked in this particular enterprise. But it cannot be said of the electric lighting industry that the profits are too large, rather the contrary; so far as balance-sheets tend to show anything they show a fair amount of work at too low a profit. The mere fact of having obtained an order for a dynamo, or for a number of dynamos, in the teeth of rivals may prove a source of gratification for the moment to the particular firm; but, if the order has been obtained by means of too low a quotation, the ultimate result may possibly be the opposite of gratifying. The prime cost of any dynamo can be calculated to almost or quite one per cent. of accuracy, so that there is not

that room for eventualities there is in the calculations for a railway or a canal. Extending the sphere of discussion from dynamos to a complete installation, it is not very difficult to ascertain when too low a tender has been submitted. For example, the consensus of opinion from practical men is against the published amounts as tendered for the City lighting. It cannot for a moment be supposed that the men who have every inducement to support the progress of electric lighting would utter an adverse criticism if it were possible to restrain it. The same line of argument may be pursued in regard to all electrical apparatus. Just as the prices of the best makers of steam engines are approximately the same, so the prices of the best makers of dynamos must also tend to an average. The slight differences there must be will easily be accounted for, inasmuch as one maker will profess to give a detail or details differently to other makers, and maintain that this peculiarity really makes his machine better and cheaper than that of a competitor whose catalogue price for a similar machine is £5 or £10 lower. Output for weight is not the best method of judging the value of a dynamo. Some members of the profession have no other idea than the machine which gives the greatest output for the least weight is the best. They are wrong. Prices may at first be diminished by the use of too small a quantity of metal; but depend upon it the maintenance will involve a heavier outlay, and the total cost will be more greatly increased than when due attention is paid to the "factor of safety." Another question which as yet has received very little attention even by the most practical firms, is the cost of selling or, as it may be put, the cost of obtaining orders. As competition increases this will bear a considerable percentage to the selling price of the article. We could give a number of specific examples, but it will perhaps be best to cite cases altogether outside our particular industry. One case before us shows the cost of obtaining the order to be between 30 and 40 per cent. of the nett price received for the executed work; the payment for which in most cases extended over a period of 18 months. Another case to the point is where the traveller's salary and expenses came to about £1,000 a year, with returns to about £11,000 to £12,000 during that period. The above amounts are exclusive of advertising expenses. The first case applies to a company in which these expenses are nil—the latter to a company almost or quite the largest advertisers in the world. It will be seen that, without a complete knowledge of the percentage to be added on in the second case, comparison is difficult. However, it may be said that, with every addition made, the percentage cost of the latter was less than *half* that of the former. It is this cost of selling that is seldom taken into account by new firms; and in their innocence they

imagine they can easily undersell the older firm by 10 or 15 per cent., this, say, being the amount it costs to sell. Perhaps the eyes of some will be opened by these remarks; at any rate we sincerely trust those who think of underselling their trade competitors will think seriously over the matter before taking a leap which may prove to be too much a "leap in the dark."

ELECTRO-METALLURGY.

The subject of electro-metallurgy, taking this term in its widest signification, is of considerable importance actually, and of immense importance prospectively, not only to manufacturers of dynamo machines but to the rising generation of professional electricians, in whose hands it places almost unlimited opportunities for useful work. It is, however, one which has been, comparatively speaking, neglected by scientific journalism; for, even in the columns of the short-lived *Electro-Metallurgist*, little or no attention was given to such wide applications as those of the electrolytic refining of metals, treatment of ores, and manufacture of chemical products; and the above-mentioned term was apparently taken in its limited sense of the electro-deposition of metals for protective and ornamental purposes. We think it probable that this neglect, justified in some cases by the system of secrecy which has prevailed in certain works—as for instance in those of the *Nord-deutsche Affinerie* at Hamburg—has reacted injuriously on the applications in question, by depriving them of the interest and initiative they might otherwise have awakened, and rendering impossible any useful suggestion on the part of the theoretical electro-chemist or the electrical engineer. We have heard of cases where some such suggestion might have entirely altered the aspect of affairs—where, for instance, energy was expended in converting a *ferric* into a *ferrous* salt at the cathode and in undoing this work at the anode, or where the practical advantage of equalising the resistances of the dynamo and of the external portion of the circuit was entirely lost sight of. For these and other reasons, we are fully disposed to devote some portion of our space to the consideration and discussion of those applications in which electro-chemistry is involved, and which have hitherto been generally regarded as being of too tentative a character to be compared in interest with such applications as telegraphy and electric lighting.

The treatment of this subject might advantageously, we think, be commenced by certain eliminations—by examining in what directions anything like an industrial application on a large scale would appear to be clearly prohibited by theoretical considerations, *i.e.*, by ascertained facts which have been generalised into laws. The waste of energy and

means in directions which to some may appear full of promise, but which investigation has already shown to be hopeless, the negative work which is more detrimental than inactivity, is above all things to be deprecated and avoided. From it, however, when consummated, may be obtained useful warnings, even more emphatic than those of theory; and the record of past failures is often more interesting than that of past successes, since it leaves open the path of future progress whilst indicating the directions to be avoided.

In regard to the amount of attention and space which will be devoted to the subjects referred to, we shall of course be guided by circumstances. We can do but little, comparatively, without the co-operation of recognized authorities in the domain of electro-chemistry and of practical workers therein; and one of our objects in penning the present article is to invite and secure such co-operation.

ELECTRIC LIGHTING OF THE CITY.

At the meeting of the Commissioners of Sewers, held at the Guildhall on Tuesday,

Mr. BRIDGMAN brought up a report of the Streets Committee, recommending that the proposed contract with the Anglo-American Brush Electric Light Corporation, for lighting a district of the City by means of electricity, be not further proceeded with. He said this report was in consequence of the important statements and proposals submitted to the Court when the question was last discussed. The committee considered it necessary to inquire into those proposals, and before doing so, they would like to clear the ground. He hoped the Court would not take this to mean that they intended to shelve the question, for such was not the case. Hitherto they had proceeded on wrong lines. The committee hoped to lay down certain conditions on which the various companies would be asked to give a price, then they would be able to judge which would be the most satisfactory proposal. The committee were anxious that no time should be lost.

Mr. C. T. HARRIS could not quite agree that the report was in consequence of proposals made at the previous Court. It was in consequence of the belief that the proposed contract with the Brush Company was wrong in principle and did not protect the rights of the City. It was never intended by Act of Parliament that the Commission should have power to grant a monopoly, but simply a prohibitory power. The only proper way was to go to the Board of Trade and get a license for seven years.

Mr. TRELOAR hoped the committee would take this matter into consideration at once.

Mr. J. C. BELL was very sorry to see this report brought up by the Streets Committee. They had got a new Streets Committee, who would take some time to master the difficulties of an electric lighting contract. There was only one company with a backbone able to carry out such a work as this.

Mr. MORTON said the committee were in favour of electric lighting if it could be obtained on terms fair and just to the citizens.

Mr. BRIDGMAN said all they undertook to do was to make inquiry, and it might be that the Brush Company's proposal would be the best.

The report was adopted.

Telephony.—It is stated that telephonic communication between Vienna and Prague and between Prague and Brunn will be opened in the course of the year.

ELECTROLYTIC DISINFECTION OF CRUDE ALCOHOLS.

Some interesting information as to the processes employed in France for the disinfection, prior to rectification, of the "low wines" obtained by the distillation of fermented extracts, obtained from a variety of vegetable substances containing sugar or starch, has been given by M. Ponthiere, of the University of Louvain. By means of the electrolytic process of M. Naudin, the alcohol obtained from beet, for instance, affords on rectification a spirit free from the very objectionable flavour which usually characterises the spirits from this source, whilst the "low wines" obtained from the *topinambour*, or Jerusalem artichoke, which otherwise it would be impossible to utilise, afford by this method a spirit equal to that obtained from maize.

The first attempt in this direction, the process of M. Eisenmann, did not bring electrolysis into play, although it involved the use of electricity. This inventor passed a stream of ozonised air through the liquid to be disinfected, at a temperature of 70deg. Cent. The ozone is produced by passing air through a glass tube placed between two armatures which are in contact with the poles of an induction coil. Although certain deleterious constituents of the liquid are oxidised by this process, it has apparently no effect upon the aldehydes which are the principal impurity in the crude spirits to be treated.

According to the process of M. Naudin, the liquid is first hydrogenated by means of the zinc-copper couple of Gladstone and Tribe. In the installation of M. Boulet at Riquenne-lez-Rouen, tanks of wood or of iron, containing a number of zinc plates, alternately flat and corrugated, are employed; the weight of zinc in a tank of 150 hectolitres* being 6,200 kilos., the number of sheets 105, and the hydrogenating surface 1,800 sq. metres. Copper is deposited on the zinc from the sulphate of the metal, which is dissolved in the weak spirit to be purified. Five solutions containing $\frac{1}{4}$ per cent. of the salt are successively employed; the total weight of sulphate of copper decomposed being 20 kilos. per 100 sq. metres of zinc surface, or 360 kilos. for the tank of 150 hectolitres.

The temperature at which the deposition of the copper is effected is a point of importance; it should range from 30deg. to 35deg. Cent. Below 30deg. the action soon ceases, above 35deg. it is too violent, and the copper is non-adherent. The deposition of copper from each solution takes 24 hours, five days being thus required to form the zinc-copper couple, at the end of which time the deposit is of a chocolate-brown colour. The "low wines" to be treated are run into the tank from above, and are withdrawn through a tap at the lower portion of the tank into a reservoir, after remaining exposed to the action of hydrogen from six to 48 hours, according to the amount of the aldehyde (alcohol dehydrogenated) contained in them.

By the action of the zinc-copper couple, hydrated oxide of zinc is produced, and this must be removed about every eight days by the addition of about 5 kilos. of hydrochloric acid to a charge of 150 hectolitres of "low wines." After each treatment with acid a charge of 150 hectolitres containing 5 kilos. of sulphate of copper is introduced into the apparatus. By this means the latter may be kept in working order for 18 months or two years. The treatment of the crude spirit by the zinc-copper couple ordinarily suffices for its disinfection by the conversion, through the action of hydrogen, of the whole of the aldehydes into their corresponding alcohols; but in certain cases it is advisable, in consequence of the presence of other impurities, to subject the fluid to electrolysis prior to rectification.

The voltameters in which this electrolysis is effected are composed of cylindrical glass vessels 125 millimetres in diameter and 600 mm. high, provided with ebonite covers, through which pass an ingress and an exit tube, and two electrodes of sheet copper. This apparatus is, in our view, susceptible of being greatly perfected. For the treatment of 300 hectolitres of "low wines" in 24 hours, M. Naudin employs 12 of these voltameters, arranged 2 in series and 6 in parallel; the liquid passing through them in two parallel streams. The following are the conditions of the treatment:

* The hectolitre is 22 gallons, the kilogram 2.2lb.

Degree of acidulation of the liquid by hydrochloric acid (in volumes)	30000
Total current	36.65 amperes
Difference of potentials at the voltmeter terminals (two in series)	113.5 volts
Current through each voltmeter	6.12 amperes
Resistance of " "	9.3 ohms

The current is supplied by a Siemens' shunt dynamo absorbing 4 h.p.

To effect the neutralisation of the small quantity of acid employed, a quantity of zinc is placed in the supply tank of the rectifying still.

The following details have been given by M. Naudin as to the cost, per hectolitre of alcohol produced, of each of the above operations:—

Treatment of 200 hectolitres of "low wines" by the copper-zinc couple (in 24 hours).

Commercial hydrochloric acid, 1.25 kilo. at 6fr. per 100 kilos.	0.075 fr.
Sulphate of copper, 1.25 kilos. at 56fr. per 100 kilos.	0.70 "
Zinc consumed { by acid or sulph. of copper, 2 kilos. ... by disengagement of H, 1.5 kilos. }	at 60fr. 2.10 "
Labour, 24 hours	7.00 "
Motive power.	2.00 "
Maintenance and repairs	1.50 "
Amortisation of 15,000fr. in 10 years	4.50 "

Total..... 17.875 fr.

Electrolysis of 200 hectolitres of "low wines."

Hydrochloric acid $\frac{3}{10000} = 6$ litres	0.438 fr.
Zinc to neutralise acid, 4.5 kilos.	2.61 "
Motive power, 4 h.p.	8.00 "
Labour, 24 hours.....	7.00 "
Maintenance and repairs	1.50 "
Amortisation of 15,000fr. in 10 years	4.50 "

Total..... 24.048 fr.

CORRESPONDENCE.

CENTRAL STATION LIGHTING AT BERLIN.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR, -In the notes of your last issue of the 2nd March, under the title "Berlin," quoted from *Industries*, description of our central station (No. 37, New Friedrichstrasse), the readers of your valuable journal are misled by the statement.

The Babcock boilers were made in Glasgow and not in Kustrin; besides two Davey-Paxman's compound engines of 35 effective h.p. each, there is one 10 h.p. of the same firm, the two dynamos of Mather and Platt are not of 18 kilo watts, but of 20 kilo watts each; the accumulators are de Khotinsky patent, and not pattern; their capacity 1,200 ampere-hours and not 600. This central station is made for 1,250 incandescent lamps of 150 volts 16 c.p., and not for 500 lamps, and the lamps are "de Khotinsky" and not "Seels." All complete cost £4,000 instead of £3,500 mentioned, which will make per lamp £3 2s. instead of £7 stated by *Industries*.—Yours, &c.,

CAIT. A. DE KHOTINSKY.

ALTERNATING CURRENT ELECTRIC MOTORS.*

BY DR. LOUIS DUNCAN.

The alternating system of electrical distribution, possessing as it does many advantages for distributing electrical energy over extended areas, possesses certain disadvantages, among others that of not, at present, allowing the use of electric motors for the distribution of power. Let us, before taking up the special subject for consideration to-night, briefly review the general subject of alternating current distribution.

* Paper read before the American Institute of Electrical Engineers, February 14, 1888.

In this system are employed currents of high and constant potential, varying from positive to negative many times a second. If we represent current and potential by curves whose heights above a horizontal line represent amperes or volts, the horizontal distance representing intervals of time, we will have something like the following: Fig. 1, I representing current, E representing electromotive force, the maximum value of the current lagging behind the maximum of E.M.F. in a way that you were shown recently by Mr. Stanley.

The high potential used in the dynamo or primary circuit would not be suitable for incandescent lighting and would be dangerous; it is, therefore, reduced to a low potential at points of consumption by "transformers," that is, induction coils working backward. Now, the whole beauty of the system lies in this—that by using high potentials in the primary circuits we can transmit a great deal of energy with comparatively little current, and, therefore, with little loss in the lines. This enables us to use small conductors, and to avoid the large investment in copper necessary in distributing energy by the direct system.

FIG. 1.

In any central station supplying electric lights, the full capacity of the plant is utilised but a short time during the day, and taking the whole twenty-four hours we will find that we have sold an amount of energy equal to a half or a third—perhaps even less—of the amount we could supply, supposing there was a demand for it all. Let us represent by a curve, Fig. 2, the amount of current used during the day in a constant potential system, the potential being constant, the energy will vary with the current, it being equal to C.E.

The amount of energy we could have sold is represented by the total area A O X B, the amount we have sold is the area D E F G H I X O. If we had been able we would have three times the receipts, with expenses perhaps half again as much as in the first case.

A great problem before electricians is to fill the vacant spaces, A D E F G H I A and H I B. There are two ways to partially accomplish this. Suppose, in the first place, we put electric motors on the circuits and sell power during the day. What effect will that have on our diagram? If the motors are at work from 7 a.m. to 6 p.m. we can sell so much power as will at no time make the sum of the power and the energy used for lights greater than the maximum capacity of our station. The area representing the power we can thus sell is shown by G K L M on the diagram. The total solid part of the diagram is all that an alternating system can supply. The direct system could fill the entire area by using storage batteries.

FIG. 2.

Our knowledge on the subject of alternating currents is largely due to the work of M. Joubert and Dr. John Hopkinson. The latter showed first that alternating dynamos could be coupled in parallel, and afterwards that one dynamo could be used to drive another as a motor. He brought forward experiments tried by Prof. Adams and himself, in which one dynamo had driven another, the latter doing mechanical work. Mr. Siemens at the same time, in 1885, described experiments where he had driven both alternating dynamos and ordinary series motors by alternating currents. Dr. Hopkinson's mathematical work assumes that the curve representing E.M.F. is a simple sine curve; that is, that $E = E_0 \sin 2\pi \frac{t}{T}$; it is important to notice,

however, that his principal conclusions do not depend upon this assumption, but would be true if the E.M.F. were any periodic curve. Since that time nothing of importance has appeared on the subject excepting two short papers, one by Mr. Kapp on "The Maximum Work Obtainable from a Given Source of E.M.F.," the other by Mr. Blakesley on "Conditions of Maximum Efficiency in the Case of Transmission of Power by Alternating Electric Currents."

In all of the mathematical work done on this subject it has been assumed that the various E.M.F.'s may be represented by a sine curve, and that only simple electro-magnetic actions enter into the problem. I do not believe that these assumptions are

true. Since Joubert's experiments, made in 1881, it has been known that the curve of E.M.F. of a Siemens alternating dynamo, where the external circuit had no static capacity, was very nearly a sine curve. With some of the machines used to-day, and under the much more complicated conditions of distribution, this is probably not even approximately true. Neither is it true that the static actions of the different forms of wire upon each other in the transformers can be neglected. Messrs. Hutelmaon, Wilkes, and myself have lately experimented on this subject, and we have obtained the curves for the currents in the secondary and primary circuits under many conditions. These observed results do not agree with the results of calculation in the few cases that we have worked out. Until we have fully satisfied ourselves in this matter I will avoid any but the simplest mathematical work.

Alternating current motors are not in successful use. Let us try to find out the difficulties they present, and attempt to suggest plans for overcoming them.

FIG. 3.

The energy being transformed at any moment in any dynamo-electric apparatus in which I include dynamos, motors, transformers, &c. is equal to the product of the current by the electromotive force produced by the apparatus. In a dynamo, for example, the amount of mechanical energy being transformed into electrical is $E \cdot C$, where E is the electromotive force produced by the dynamo; in a motor the electrical work transformed into mechanical is $E \cdot C$, where E again is the E.M.F. produced by the apparatus, the counter E.M.F. of the motor. This is true for alternating as well as for direct current apparatus. Generally we have:

Work = $E \cdot C$. This is + for a dynamo - for a motor.

In alternating circuits E and C are constantly changing. If we represent them by curves, as before, we must multiply each value of C by the corresponding value of E , and if we add all these together from A to B , Fig. 3, we will have the work done by the current in one period. Now if we consider values above the horizontal + and below it -, we have from e to d a + value of the product, from c to d a - value, from c to b a + value, from b to a -. The total work done then is $[e \text{ to } d] + [c \text{ to } b] - [d \text{ to } c] - [b \text{ to } a]$.

Now we see that if we shift I forward or pull I back, we have this work less even, though the curves themselves remain the same size. Now this is one of the exceptions I take to the alternating system. In a direct system as the work decreases the current decreases, and the heating of the mains becomes proportionally less, since it varies as C^2 ; for example, if the maximum loss in the mains of a direct current plant were 10 per cent. of the average, I imagine that the average loss is not over 3 per cent. In an alternating current plant, a decrease in the consumption of energy decreases the current very little, it

FIG. 4.

simply shifts its position with respect to the E.M.F., and the heating, approximately equal to $\frac{C_0^2}{2} R$, remains nearly constant.

A maximum loss of 2.5 per cent. would probably mean an average loss of at least 2 per cent. This same remark applies to transformers and motors, and the average efficiency of the former will be considerably less than the maximum efficiency.

A distinction between continuous and alternating current apparatus is this: In continuous current dynamos and motors the cores making up the windings of the armatures make different angles with the lines of force in the field, and the result, when the armature rotates, is a constant E.M.F. fluctuating but little; in alternating dynamos and motors the alternate coils are symmetrical with respect to the alternate poles, the remaining coils being symmetrical with respect to similar poles of opposite signs. The result is a varying E.M.F., changing as has been shown. In dynamos the effect of this is that the power applied either varies from zero to a maximum each period, or the armature changes its speed at different points and oscillates with a period equal to that of the E.M.F.

Let us now consider what takes place in the case of two motors, one continuous, the other alternating, one between mains where a constant continuous E.M.F. is maintained, the other where there is a constant alternating E.M.F. In the first case representing current and E.M.F. by curves, as we have been doing, we will have two straight lines, Fig. 4, one above, the other below our horizontal axis, the former representing current, the latter the counter E.M.F. of the motor. Reckoning time along the axis we have for the energy transformed in the interval from a to b - $C \cdot E$. As this is - it means that electrical is transformed into mechanical work.

Now, let us consider an alternating current motor built like an alternating dynamo, the field excited by a continuous current. If $A B C$, Fig. 5, are the poles of the field magnets, supposed to be excited by a continuous current, then the curve $I I$ will represent the counter or motor E.M.F. If our motor is running slowly there will be two or three reversals of current in the time it takes a coil to go from A to B , Fig. 6, and the product $C \cdot E$ will be nearly zero, the positive and negative parts being

FIG. 5.

almost equal. Whether it is + or - is somewhat a matter of chance, and if it is - from A to B it will very likely be + from B to C . Thus the armature is pushed first in one direction, then in the opposite, and there is no definite tendency for it to rotate as a motor. This brings us to our first difficulty, a simple alternating current motor will not start itself. Let us suppose, however, that it has been started by some means and has reached such a speed that in the time of a reversal a coil shall have moved over the distance between two similar poles. We will have the state of things in Fig. 5, and the armature will continue to rotate. Now, the position of the curve $I I$ is fixed. We will consider the position of I as determined by the position of the armature coils when the current in them is zero - for instance, if the speed increases a little the curve will advance as shown by the dotted line. The total work transformed is the product of the two curves; from 1 to 2 it is +, from 2 to 3 it is +, from 3 to 4 -, from 4 to 5 +. The result is $-(1 \text{ to } 2 + 3 \text{ to } 4) + [2 \text{ to } 3 + 4 \text{ to } 5]$; part of the time then the machine is working as a dynamo, part of the time as a motor; the difference of the values represented by the brackets gives the mechanical work that is really available. Now, while the available work is the difference of these areas, the difference becoming small as the load is decreased, the heating is the sum $C^2 R$ for all the values of the current, and is independent of the position of its curve, as has been pointed out above.

Looking at the figure again we see that from 1 to 2 the armature is pushed forward by the current in the line; from 2 to 3 it is pulled back, since it is acting as a dynamo feeding into the line and can only get the energy to produce the current by decreasing its speed and drawing from its energy of motion. The armature oscillates then, and it is evident that the amount of

FIG. 6.

its oscillation depends on the kind of work it is doing. If it is driving heavy wheels or machinery having considerable inertia it will only have to slow down slightly when it becomes a dynamo. If it is lifting weights the amount of oscillation will be considerable.

It is evident that there is a certain position of the curve I that will make the available work a maximum. If the motor is doing all of its possible work the curve will take up this position; as the load is decreased the speed will increase for an instant, until the curve has shifted forward into such a position that the sum of the products - $E \cdot C$ is equal to the work done. In fact, we can plot a curve representing values of the distance from the point the current curve crosses the axis to the same point when the work is zero corresponding to different loads.

Now the value of this lag, as we will call it, cannot be greater than $O P$, Fig. 7, for although we might extend our curve on the other side, yet a slight increase in our load will cause the armature to fall back, decreasing the available work, and suddenly stop. It is, in fact, an unstable equilibrium.

Suppose we have found the value of the lag that will give us

a maximum value of the work, and have calculated this value by the ordinary mathematical methods employed, the real work we can obtain is less than this, for the current curve oscillates on both sides of the maximum, supposing we could work at the maximum; that is, it is only for a very short time in the best position; so that if we take the sum of the work for a period, it will be less than the calculated maximum. In reality we must work slightly in advance of the maximum, for if we were too near it the curve would fall behind P, and will then be in unstable equilibrium and stop. The practical maximum will then vary according to the amount of the oscillation; that is, according to the nature of the work being done.

It seems to me that the possible forms of alternating motors are: (1) Ordinary series motor; (2) an alternating dynamo reversed, the field being excited by a continuous current; (3) an alternating dynamo reversed, the field being excited by the alternating current first corrected by a commutator on the shaft; (4) the arrangement suggested by Professor Thomson, which is described below.

FIG. 7.

In the first type—a series motor—there is no difficulty in starting; the motor will start of itself. There are these troubles, however: the armature and field must both be thoroughly laminated to prevent eddy currents; the magnetism of such large masses of iron being rapidly reversed will cause losses, unless both field and armature are far from saturation—that is, the mass must be great. Again, Mr. Kapp has shown that to obtain the maximum work we must have, approximately, the counter E.M.F. of the motor equal to the E.M.F. of self-induction—a condition almost impossible to realize in practice. The motor must be governed in some way, as it will not govern itself.

The alternating motor with a field fed from the alternating current, the current being commutated, will start itself. I do not know if this has been generally recognised. If, in Fig. 8, A and B are poles, and C one of the armature coils, the effects of the currents will be as shown by the two sets of signs. The effect of either arrangement is to move the armature in the direction of the arrow. When C gets opposite A the commutator changes the relative directions of the currents in C and A, and C is repelled by A and the armature continues to rotate. The maximum work will, I think, be done when the speed is such that a reversal takes place in a distance A to B. The mathematical investigation is difficult, and until I am satisfied as to the assumptions usually made I will not attempt it. We have as an advantage of this type that it will start itself; a disadvantage is that the field must be carefully laminated, there is loss in reversing them, and there will be for some speeds considerable sparking at the field commutator. I should not imagine, either, that the work obtainable from such a motor would be as great as if its field were fed by continuous currents.

FIG. 8.

The motor obtained by reversing an ordinary alternating dynamo has advantages and disadvantages. It perfectly regulates itself, and the field magnets need not be laminated; that is, it can be made cheaply. It will give a greater output from a given source of current than corresponding machines of either of the types already discussed. Its disadvantages are that it must be started independently. We must have a continuous current to excite the field, and, if a load having any considerable inertia is suddenly applied, the motor will stop. This last objection, by the way, will apply to the type of motor previously discussed; provided, as I have supposed, the maximum work is obtainable when the counter E.M.F. has same period as the applied E.M.F.

Let us see what means we can employ to start the motor and excite the field. We could start by passing the commutated alternating current through the field as in the second type of motor discussed, changing our connections when the proper speed is attained, so that a continuous current from some external source passes through the field and the alternating current is shut off from it. Another way would be to have on the same shaft with our main motor a motor arrangement such

as was described by Prof. Elihu Thomson in his valuable paper on alternating current phenomena, read before the Institute. With this arrangement we can do more than start the motor. Prof. Thomson pointed out that when this auxiliary motor reached a certain speed it would produce a continuous current in the external circuit of its armature. This current could be used to excite the field of the main motor. By properly proportioning the number of coils in the main and auxiliary motors, this continuous current would be produced just when the motor had arrived at its proper speed, and it is evident that we can make this current operate an automatic device to make the circuit of the main motor at this moment. I should imagine, however, that a motor made in this way would be expensive and not particularly efficient.

(To be continued.)

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

At the meeting of the Society of Telegraph Engineers on the 16th ult. Mr. W. H. Preece, presiding, the discussion was commenced on the papers of Messrs. Kapp and Mackenzie on 'Transformers.'

Prof. Ayrton agreed with Mr. Mackenzie that credit was due to Messrs. Gaulard and Gibbs for having drawn attention to the method of distributing electrical energy at the Aquarium Exhibition of 1882. No one who had seen the secondary generator at the Aquarium would have thought in a short time this system would be so largely used for the distribution of electrical energy in the country. Probably some did not appreciate the use of transformers, because the measurements that they had seen were unsatisfactorily made. Even the system might be as deficient in satisfaction as the way used for measuring its efficiency. Of course, the speaker remarked, that in no manner lessened the value of transformers. For example, the potential difference at the terminals of the transformer was measured by a high-resistance dynamometer, and that was measured by the current measured by a low-resistance dynamometer, and the conclusion at once was that the product measured either the watts put in or the watts given out, and in this way an efficiency was arrived at, which might or might not have some connection with the true efficiency of the transformer. In this experiment two errors were made, viz., to measure alternating volts with a high-resistance dynamometer was wrong, and to multiply the volts, even were they measured correctly, by the current would not give the watts if the current contained self or mutual induction, any more than the mean pressure of the steam in a cylinder multiplied by the number of revolutions per minute gave an answer proportional to the horse-power given by the engine independent of the time the steam was cut off at each stroke. Nevertheless, it did seem that the system was an extremely good one, the fact being proved by the extensive use of it in the United States. The next point in consideration was the danger of lives in touching the secondary, which might easily be avoided by putting an wire of every secondary to earth without affecting the primary circuits in the least, whilst it ensured perfect safety in the secondary arrangement without the use of any particular fuses or automatic motive device. It also had this advantage—that it prevented their getting a shock from the electrostatic capacity of a transformer, which might be considerable. It had been rather held by the authors of the papers that it was impossible to use transformers in series if they wished to maintain constant potential difference at the terminals of the secondary when the resistance of the secondary circuit was altered, that is to say, if the number of lamps in parallel in the secondary circuit was varied. There was, however, a method of producing a constant potential difference in the secondary with constant mean alternating current in the primary, which it appeared to him would lead to good

FIG. 9.

results. The method was analogous with the compound-wound dynamo. In a compound wound dynamo they had a series coil, which increased the magnetisation of the field magnet when the current of the outside circuit was increased. They would get exactly the same thing with transformers. Supposing the secondary coil S (Fig. 9), was joined in the ordinary way to the lamp L, let there be in addition a second induction coil, S T, the primary of which S was in series with S and the secondary T, so joined up that it added a potential difference to the secondary circuit and added the greater potential difference the greater the current passing through the secondary. That arrangement was exactly the arrangement of a compound-wound dynamo, the tertiary coil would correspond to the series coil of the compound wound dynamo. That was to say, a constant current passing through the primary coil P, would produce a constant electromotive force in the secondary S, and a potential difference would be added to the secondary circuit, the added potential difference being the greater the greater the current in the secondary circuit S. At any rate, he believed it might be possible by such an arrangement to do this, and so obtain a transformer capable of working in series. That idea occurred to his colleague and himself some three or four years ago, but as they found great difficulty in working out the results in the primary, secondary and tertiary coils mathematically, they thought they should do better by resorting to experiments. An apparatus

KAPP AND SNELL TRANSFORMER.

Experiments made at the Central Institution by Messrs. DYKES, LAMB, PRIEST, SMITH, and ZINGLER.

Primary.		Secondary.		Calorimeter.	Watts given out by Secondary.	Watts given to Primary.			Efficiency.

186.1	8.31	94.4	14.87	55.6	1416	1472	1546	1727	96.2	91.5	82
185.6	16.14	91.44	30.59	149.9	2813	2963	2995	3277	95.0	88.7	85.9

Each test given in the above table is the mean of five or six consistent results.

Efficiency $\frac{100 h}{\sqrt{a^2 \times b^2}}$ neglects the lag due to the self and mutual induction of the transformer.Efficiency $\frac{100 h}{f}$ neglects the lag due to the self and mutual induction of the transformer: also the lag in the fine wire coil of the watt meter due to its self induction.Time of an alternation in all the experiments was about $\frac{1}{50}$ th of a second.

was made, and, indeed, it was for these experiments that the little volt meter, which they brought before the Society at the end of last year was originally devised. Their transformers were little things, and so they found it was necessary to measure a few volts—alternate potential difference—accurately, and therefore they wanted a voltmeter to measure four or five alternate volts accurately. When their experiments were about to start he came across an account published, if he remembered rightly, by Messrs. Gaulard and Gibbs, putting forward exactly the same device which those gentlemen had then just covered by a patent. He would be very glad to hear from Mr. Mackenzie whether this system was seriously tried. Had he not come across this description of a precisely similar method of compounding transformers, he and his colleague would certainly have pursued the matter, but they left Messrs. Gaulard and Gibbs to do it, and, curiously enough, nothing more had been heard of it. He was very glad to see that the idea of magnetic lag, which means a retardation of iron to be magnetised, was gradually gaining acceptance, especially in consequence of the admirable work that had been done in this subject by Prof. Ewing. The idea of magnetic lag, quite apart from Foucault currents in the iron, was put forward some years ago in that room in the paper, prepared by himself and his colleague, on electromotors and their government, and the conception was used in all the calculations they made. This conception was somewhat laughed at by writers in some standard books. Their names were held out to reproach as having brought forward an idea of a magnetic lag which was something different from a lag due to Foucault currents, and which could not be entirely removed by any amount of lamination. Now, however, that the Greek name *hysteresis* had been given to the lag, the classically educated English man was willing to believe in it.

FIG. 2.

He had spoken about wrong ways of making measurements of the efficiency and power given to transformers. Now, he would say a word about the right ways of making such measurements. He was interested in doing this because, through the kindness of Mr. Kapp, who had lent him one of his transformers some time ago, a considerable number of experiments had been made by the third year students at the Central Institution during the past few weeks. The students had worked at the subject with the most laudable perseverance, in spite of the very considerable number of difficulties which they had to overcome. There was only, as far as he knew, one electric method for measuring the power given to a circuit which contained self or mutual induction. The method was a method employing the quadrant electrometer. It was a method which Dr. Hopkinson employed in measuring the efficiency of Gaulard and Gibbs' transformers on the Underground Railway some few years ago. Let A B (Fig. 2) be the circuit possessing self or mutual induction, or both, the power given to which it is desired to measure. Place in series with this a non-inductive resistance, B C, of known value r ohms, and send a current through the two by means of the dynamometer D. Join the pairs of quadrants of an electrometer to the points A and B, and the needle to C, then if A, B, and C represent the potentials at any moment of the three points, and if D be the steady deflection of the electrometer

$$D = \frac{k}{2\tau} \int_0^\tau (A - B) \left(C - \frac{A + B}{2} \right) dt,$$

where τ is the interval between two alternations. Next, join theneedle to the point B, and let a steady deflection, d , of the electrometer be now obtained; then

$$d = \frac{k}{2\tau} \int_0^\tau (A - B) \left(B - \frac{A + B}{2} \right) dt.$$

Consequently,

$$\frac{D - d}{r k} = \frac{1}{2\tau} \int_0^\tau (A - B) \left(\frac{B - C}{r} \right) dt.$$

Now the expression on the right hand side is the mean value of the true watts given to the circuit A B, therefore $\frac{D - d}{r k}$ measures this mean value of the true watts.

It was rather interesting, because this method occurred simultaneously to Prof. Fitzgerald, of Dublin and to the speaker during the Paris Electrical Congress of 1881, while listening to M. Joubert's paper on the measurement of alternating volts with an electrometer, which, of course, was a very much simpler thing. The use of the electrometer to measure volts only did what a Carlew voltmeter would do. The use of an electrometer to measure power, given by an alternating current to a circuit possessing self or mutual induction, did what no other instrument would do. But though the method was theoretically perfect, it had distinct practical objections. The first objection was that another resistance B C (Fig. 2) had to be put in series with the conductor A B, in which the power expended was to be measured, and, of course, a certain amount of power was wasted in this wire, B C. That did not interfere with the accuracy of the experiment in any way, but it might be inconvenient to have to waste any power in a circuit previously worked up to its limit. But there was another more serious objection which he was not aware of up to the last couple of years. Their formula was worked out on the assumption that the ordinary law of the electrometer, as given, for example, by Clerk Maxwell, was true. The law of the electrometer as given by Clerk Maxwell, was that the deflection of the needle of an electrometer was proportional to the difference of potentials between the quadrants multiplied by a term containing the potential of the needle, minus half the sum of the potentials of the quadrants. Unfortunately, as experiments made at the Central Institution had shown, it was an exception for any given electrometer to satisfy this formula. He would not go more into that at the present time, because it would form the subject of a subsequent communication. He merely wished to warn any of them who were going to use the electrometer that, although this method was perfect on the assumption that the formula given in books was the formula for the electrometer, it naturally was not so perfect if the formula was wrong; so that even this method, just as it was, was at fault. Well, then there was only one other method that he knew of by which they could measure the power and efficiency of a transformer, and that was the calorimetric method. They wanted to measure the power given to the transformer, and the power given out by the transformer. The power given out by the transformers could be easily measured. The secondary current would give current to, say, incandescent lamps, and as there was no lag in this part of the circuit the power could be measured merely with a voltmeter and dynamometer. But they could not employ that method to find the power given to the primary. They could, however, do it indirectly in this way. Put the transformer in a calorimeter, first put it in a box, close it up water-tight then put it in another box, which must be water tight at the bottom, but need not be water tight at the top; arrange a definite resistance in the secondary circuit, and send a definite current through the transformer for a certain time, and allow water to enter, say, at the bottom of the calorimeter and to flow out at the top, and measure the temperature of the entering water with a thermometer and the temperature of the water which leaves, and keep the current flowing until everything has become quite steady—until the temperature of the water as it flows out of the calorimeter ceases to rise, which in some cases took as long as three and a half hours. Then, quite apart from the specific heat of the transformer and the calorimeter, and so on, they had at once the power wasted in the transformer. Supposing W was the weight of water in grammes which flowed out of the calorimeter in a time of, say, t seconds, and suppose T was the difference of tempe-

ture between the entering water and the leaving water, which he had expected to have become quite steady, then the power in watts wasted in the transformer and given out in the form of heat was equal to W , the number of grammes of water, multiplied by difference of temperature T divided by the time in seconds t into a constant 239. That gave them the power in watts that was wasted in the transformer. That added, of course, to the power given out by the secondary, which was obtained by electrical measurement, gave them the power put into the primary, and they had then the whole measurement with a considerable amount of accuracy. Let him repeat, power given out by the secondary was accurately measured, provided that the secondary was attached to incandescent lamps or to something having no self-induction nor mutual induction, by the square root of the mean square of the volts multiplied by the square root of the mean square of the current, that was to say, measured by the reading of the Carlew voltmeter multiplied by the reading of the Siemens dynamometer. That was the power given out in watts. The power wasted was measured by the formula already given. The ratio of the watts obtained in secondary to the sum of the two is of course, the efficiency. Well, that method had given them very fair results. He had compared these readings with those obtained by putting a dynamometer and a voltmeter on the primary circuit. For the interest of the thing, they had also an ordinary wattmeter in circuit, the clock coil in series with the primary, and the fine coil a shunt to the mains. Now, it was interesting to see the sort of results that were obtained on the different systems of measurement, especially as they knew when results were true and which results were more or less correct. In the first case, the circuit outside was broken—that is, there was no current in the secondary circuit. This particular transformer was an exact *for example* of a small transformer which Mr. Kapp had on the table last time. He might mention that Mr. Kapp's mode of rating transformers was an extremely satisfactory one. Very often when a new apparatus was devised the nominal power was stated in excess of what the real power was. But transformers, at any rate Messrs. Kapp and Snell's transformers, were on a par with the steam engine, and that was that the real power developed was far greater than the nominal. He did not know whether his dynamos were equally good, but if so they must be extremely good. This was the two horse-power transformer nominal, which did not mean, he was happy to say, that it gave one horse-power. It meant that you could get three out of it, or even four without undue heating appliance. In the first case the volts at the primary circuit were 184.5, the volts at the secondary—the circuit being open—were 94.5. Now let them see the enormous difference of the power as measured in the different ways. The watts put in as measured by the voltmeter and dynamometer were 147. The watts put in as measured by the wattmeter were 98.5. But the actual power put into the whole circuit was only 53 watts. Therefore the two last were enormously too large, and they could see why they were too large. They were too large because when the secondary circuit was broken, the effective self-induction of the primary coil of the transformer was very much larger than when the secondary circuit was closed, and the errors of both methods became immensely magnified. Of course, in this case, since the secondary was open, all the power put in was wasted in the heat. But the real watts given to the primary, as determined by the calorimeter, was 53.2. The other methods indicated then, about from two to three times too much. Of course, as the secondary circuit was closed, and less and less resistance was put in, the readings given by the the wattmeter as well as the product of indications of the voltmeter and dynamometer became nearly equal to the true watts, but they never even for the maximum power, became equal. For example, when 2,963 watts were actually being given to the transformer, which was about 4 h.p., the product of the square root of mean square of volts into square root of mean square of amperes gave 2,995 watts, while the wattmeter gave 3,277 watts as the power put into the transformer. The readings obtained from the voltmeter and the dynamometer were higher than the true watts put in, because lag, due to the self and mutual induction of the transformer, was ignored altogether. The wattmeter readings were higher than the true watts put in, because not merely was the lag due to the self and mutual induction of the transformer neglected, but the lag in the true wire coil of the wattmeter, due to its self-induction, was also ignored. That led him to investigate the question as to whether the wattmeter ought to give them an answer nearer the truth than the product of V squared into C squared; and the result that he had obtained, approximately at any rate, was this:—The wattmeter might be thought not apparently give them an answer nearer or farther away from the truth than the reading from the dynamometer and the voltmeter. A rough calculation showed this was what was obtained with a wattmeter. Take a wattmeter like a Siemens wattmeter, which had practically no mutual induction, but had some self-induction, then if such a wattmeter were employed to measure power in a circuit having self-induction this seemed to him what would be obtained. It was the time of an alternation, τ the resistance and L the coefficient of self-induction of the fine wire circuit of the wattmeter, τ and L the resistance and self-induction of the circuit of the power given to which was desired to measure, then the reading of the watt meter, compared with the true power which they wanted to measure, had this value $\frac{\tau^2 R^2}{\tau^2 R^2 + \pi^2 L^2}$. It was possible, by putting but a few convolutions in the suspended fine wire coil of the wattmeter, and using for the greater part of the resistance of the fine wire circuit a stationary non-inductive resistance, to make L the coefficient of self-induction of the fine wire circuit of the wattmeter very small; but unless it were made absolutely negligible, the term $\pi^2 L^2$ might be large in consequence of the largeness of L , and then expression would be the greater the greater L was. So that, in other words, they might expect when the current the power given to which they wished to measure had very much self-induction, that the wattmeter would give an answer far too high. In the wattmeter used at the Central Institution, the self-induction of the fine

wire circuit was made very small in the way just indicated, the resistance of the suspended coil having only 1/10th of the value of that of the non-inductive stationary coil; but still the watts given to the primary, as measured by the wattmeter, were 200 per cent. too large when the secondary circuit was open.

(To be continued.)

THE ELECTRIC LIGHTING ACT (1882) AMENDMENT BILL.

HOUSE OF LORDS, MONDAY, MARCH 5.

Lord Thurlow, in moving the second reading of this Bill in the House of Lords, on Monday, the 5th inst., said that if he could have had an assurance from the Government that they would be willing to take this matter in hand he would not have troubled their lordships on the present occasion. He desired then lordships to regard this question from the point of view of health, of science, of more light, of safety, and of the preservation of property. The object of the Bill was to remove what had proved to be prohibitive restrictions upon an industry which was deserving of every support. The restrictions imposed by the Act of 1882 had acted very harshly. The President of the Board of Trade, replying last week to a question in the House of Commons, said that once the passing of the Electric Lighting Act of 1882 59 provisional orders and 15 licences had been granted to companies and 15 provisional orders and two licences to local authorities. The President of the Board of Trade was not aware that in any single case where these powers had been obtained they had been exercised. Such was the crushing effect of the Electric Lighting Act of 1882. Still he wished to say a few words in praise of that measure, which it was the object of this Bill to amend in only one or two small but important particulars. The Act of 1882 was a most elaborate measure for dealing with a then almost unknown science. It successfully prescribed safeguards against dangers which had only since become manifest, and its object was to impose checks on rash and ill-considered schemes. It now only required tiding amendment to allow the industry to proceed, and he claimed that the time had arrived for action in that direction. In the United States there were over 120 electric light companies paying dividends from 6 to 14 per cent. in Germany there were 604 companies, and in almost every large town in Italy electric lighting was making progress. It was only in England that the science was comparatively at a standstill, and he hoped that state of things would not be allowed to last much longer. The present time was propitious for several reasons. There never was a time when a larger amount of capital was lying idle or when there was a larger army of unemployed seeking work and finding none, and by passing this Bill lucrative work might immediately be provided for thousands of men, women, and children. He thought it would not be too much to call upon the Board of Trade to make incandescent electric lighting compulsory in all mines, factories, schools, churches, theatres, hospitals, and other places where human beings congregated together. He ventured to say that when such a demand was made the Government of the day would be neither willing nor able to resist it. Many of their lordships had no doubt visited factories lighted by gas full of toiling men, women and children from 6.30 a.m. to 6.30 p.m., and had noticed the vitiated state of the atmosphere. The difference between that and a factory lighted by electricity was manifest in a moment. It was like being transported suddenly to another planet. Workmen who had been employed in factories lighted with electricity had told him that nothing short of starvation would induce them to work again in factories lighted by gas. It was the same in the case of mines. Electric lighting would minimise the dangers which now occurred through naked lights or faulty lamps. Then as to fires in the metropolis, Captain Shaw's report showed that the total number of fires in 1887 was 2,363, and no less than 671, or 30 per cent., were directly attributable to causes connected with existing systems of lighting. These figures did not include 691 fires, the origin of which was uncertain, and of these at least 30 per cent. might fairly be said to be due to the same cause. Then as to destruction and damage to property. Some of the first tradesmen in London had told him that they had effected great saving since they had substituted the electric light for gas in their showrooms and shops. It was also well known that the use of gas was very prejudicial to books, and the employment of electric light in libraries would be a great advantage. The Bill was precisely similar to the Bill which was passed by this House last Session, and it proposed to extend the licence granted by provisional order to any company from 21 years to 42 years. The period of 21 years fixed by the present Act was found to be too short, and to be insufficient to allow electric lighting companies to recoup themselves. The Board of Trade assented to this view, and this extension of the life of the Provisional Order would render the clauses with regard to the terms of purchase of less importance. He would, therefore, be willing to strike out of the Bill all reference to the purchase of the goodwill, which he understood, had hitherto been a stumbling block and a cause of opposition to the Bill. In bringing forward this measure he was solely actuated by a desire for the public interest. There existed at present a great want of employment, and yet, as was well known, there was a vast amount of capital waiting for investment. If the present Act was amended as this Bill proposed, he believed that £100,000,000 of capital would thereby find useful employment.

The Duke of Marlborough said the Bill did not appear to contain any regulations as to the laying down of the electric cables. At present these lines were growing in number, and were being run over everybody's houses without the assent or consent of house-holders, and he thought that it should be defined in any Bill dealing with this subject.

what the rights of electric companies exactly were. There had, so far as he knew, been no decision in the law Courts upon the point. At present a quantity of telephone wires were to be seen running in every direction in the Metropolis. The cables for electric lighting would be still more dangerous. They would in time become a great nuisance, and if the Acts dealing with electric lighting were silent on the point it would hereafter be said that Parliament had unreservedly conferred on these companies the right of running these cables over houses as at present. In New York, where electric lighting was more developed than here, the electric companies were bound to place their cables underground. If it were found impossible to make a similar provision in this country, still some regulations ought to be made as to the course they should follow so as to prevent them crossing and recrossing public streets as at present.

The **Earl of Crawford and Balcarres** agreed that the Electric Lighting Act required amendment, but he thought they should deal in a thorough manner with this subject and not merely with a single clause. In 1882, when the first Act was passed, a determination was formed that the promoters of electric lighting schemes should not enjoy a monopoly, and it was accordingly resolved that when cables were laid in the street of any town by an electric company its work should be purchasable by the local authority. Another provision of the Act laid down that no work should be undertaken by a company without licence from the Board of Trade or a special Act or a provisional order. These two provisions had been fatal to the measure. Licences and provisional orders had been applied for, but no work had been done. He suggested that the promoters of a scheme ought to be allowed to make their own arrangements with the local authority. Let the company pay rent for the use of the mains which they placed under the streets, and let them be absolved from the obligation of supplying light to every corner of a given district when there might be no chance of a reasonable return for their outlay. He looked forward to the day when companies would be able to lay their cables underground with a good prospect of success; but he asserted that the risks attending exposed electric mains were fewer than the risks which attended either telephon or telegraph wires. When snow fell upon an electric light main it inevitably melted, but it accumulated on other wires, with the result that serious accidents were not uncommon. He hoped that the Bill before their lordships would be read a second time. Hereafter he intended to place before them a Bill of his own.

The **Earl of Onslow** said that the Bill as explained by the noble lord opposite was much less important than it was as printed. There was a clause in the Bill which covered a great deal of ground and repealed a provision of the existing Act; but he understood that when the Bill was considered in Committee the whole of that clause would be withdrawn, in order that to the term of 21 years during which provisional orders must now run a further term of 21 years might be added. The Bill, as it was amended, did not appear likely to be productive of great harm, and he was prepared to assent to the second reading on the conditions the noble lord had suggested. He did not know whether the reason named was the only reason why electric lighting had not been more extensively adopted; but there could be no doubt that public expectation had been greatly disappointed in the matter. We had all hoped that electric lighting would have been much more largely used. Whether it was on account of the limitation in the number of years allowed to companies or the fact that promoters found themselves unable to supply the electric light at prices that would compete with gas, or whether it was on account of difficulties in carrying out the supply of electricity he did not know; but of this he was certain, that if a small alteration in the law was likely to facilitate the adoption of the electric light in London and other large towns the Government would have no objection to it. He understood the noble earl behind to intimate that he would introduce another Bill, and if that was the noble earl's intention it would be well that they should be in possession of both Bills before this was considered in committee, and that both should be considered with reference to the provisions of the Bill of the Government dealing with local authorities, which would soon be produced in the other House and which must naturally affect the powers of local authorities.

Lord Herschell was not quite sure he understood what it was the Government was prepared to assent to. As far as he could gather, it was that the Act of 1882 was to be amended by substituting 42 years for 21 years. If no other alteration was to be made, he doubted much whether the Bill would have the effect desired. In this country we had not made the advance in electric lighting which had been made in other parts of the world. He had long desired to avail himself of this important improvement, but he had found it to be utterly impossible, for the reason that the legislature had put impediments in the way of the spread of this invention which was not put in its way in any other country. He believed that in the South Sea Islands the electric light was more used than it was in London. This was not altogether to our credit. He quite sympathised with the desire to prevent undue interference with the control of local authorities, and it might be expedient to provide that local authorities should ultimately if they wished be allowed to become purchasers of electric lighting apparatus and to supply the electric light as they now supplied gas. He did not personally feel very strongly on that point; but he was not at all sure whether the balance of advantage was not against allowing municipal corporations to become trading bodies. With regard to the electric light there was danger in doing this, because in some cases their conduct might be affected by the fact that they were owners of a gas business, and the electric light would be a serious rival to gas. At all events, the power to acquire apparatus ought to be conferred in such a way as not to cripple the progress of invention and improvement. It was too much to ask the present generation to forego the advantages of electric lighting because their doing so might render it cheaper 30 or 40 years hence. He believed that the Indian Government might acquire Indian railways upon pay-

ing a price based upon the average value of the shares for the preceding seven years. It had been found that capitalists were prepared to risk capital on these terms, and possibly a similar arrangement might be found satisfactory to the promoters of electric lighting. He would urge the Government to consider whether on some such terms the adoption of electric lighting might be facilitated.

The **Marquis of Salisbury**. I sympathise entirely with the remarks of the noble and learned lord, but I cannot help remembering that he was a member of the Government which passed the Act that he has denounced with so much vigour. Laughter. When I sat exactly where he is sitting now I pleaded in vain for a greater extension of the number of years, and I prophesied the results which have actually occurred. I rather think the noble and learned lord opposite is attributing those secretaries of the Middle Ages who went about laying stripes on their own shoulders for the sins they had committed. The noble and learned lord has held up to our attention the example of the South Sea Islands in this matter; however, I am too delighted to see that the noble and learned lord recognises the difficulty to which we had ourselves to be critical as to the precise means by which liquor-vent was brought about. It is matter of regret that we have not been able to make greater use of this invention, considering the vast amount of capital we have at our disposal and the great need in our smoky towns of diminishing the unconsumed carbon in our atmosphere. Although the Board of Trade has, acting under the guidance of the distinguished statesmen who presided over it during the term of office of the noble and learned lord, to some extent, I am afraid, since that time, exaggerated the danger of liberty in this matter, it is but we should remember that we have had very severe lessons in respect of leaving uncontrolled powers to municipalities and public authorities to make binding bargains with trading companies. On the subjects of water and gas we have had very severe lessons, and we are now struggling on with the difficulties that have arisen. The noble viscount near me, Viscount Cross, was said some years ago to have wrecked the Government by the proposals he made for the purchase of the undertakings of the London water companies. We now only wish that the proposals which were then denounced could be revived with success and carried into effect. We have bound ourselves by promises to the water companies which give them a hold upon us that I do not know we shall ever shake off. Undoubtedly the price at which this essential article may be furnished must have very considerably affected the progress of sanitary measures so much required in many parts of the metropolis. We have contrived to make some agreement with the gas companies. Twenty years ago we woke up to the fact that we had allowed most improvident agreements to be made with them, that we had allowed them, on the faith of competition which did not exist, to charge enormous prices. At the present moment in regard to gas companies, we are under difficulties which could not have been foreseen by our forefathers when these terms were made, or I am convinced that the measures which they allowed to pass would have been seriously modified. The truth is that in both these cases we have made exceedingly bad bargains, and we are bound by them; and, therefore, it is not wholly unreasonable that in dealing with this new element we should approach it with some amount of caution. I quite believe we may have been too cautious, and may have run into an opposite extreme, and, by hindering the production of the electric light at the cheapest prices, may have prevented the development of this new industry. If the noble and learned lord can show us that the terms we ask can be reasonably modified, no feeling of self-love will prevent us from making any alteration which your lordships may think desirable. I think we ought not to be misled by the desire to give the municipalities control over these matters. We have a sufficient number of examples as to the capacity of municipalities to carry on the business of traders on a large scale. We know the temptations are enormous, and the danger we have to face is not that the municipalities themselves will administer these trading concerns, but that they will be in the hands of party efforts wielding an enormous and irresistible power, exposed to temptations to which the municipalities themselves will not be habit, and at the same time not having the responsibility which rests upon the municipalities. I feel that the whole question of the expediency of giving this power to the municipalities has of late years been too much assumed without sufficient proof, and we should be cautious about surrendering ourselves wholly to them and preventing that protective competition of private companies which is so desirable in the interests of the community at large.

The **Earl of Kimberley** said he remembered perfectly well that the noble marquis objected to the Bill of 1882 as being too stringent; but the latter part of the speech of the noble marquis answered the preceding part—namely, that the Government and the House in 1882 had before them evidence of the previous mistakes that had been made with regard to gas and water legislation. The Board of Trade, which was then presided over by Mr. Chamberlain, was extremely anxious that in the matter of this new invention they should not fall into their former errors. In the discussion on the Bill in 1882 he admitted that it was an experiment, and that they might possibly, by future legislation, be compelled to amend the Bill if they found that they had erred on the side of severity. It was much safer to err on that side than on the side of indulgence. With regard to the municipalities, they undoubtedly ran the risk of having too much authority, but he would point out that there was likely to be a most severe pressure put upon the ratepayers in the carrying out of improvements, and it was a matter worthy, in his opinion, of very careful consideration, whether by giving the municipalities the power to work this large invention which provided what was, in fact, one of the necessities of life, they should not be affording them a means of relieving themselves to a considerable extent of the burdens under which they laboured. It was because they wished to see this end accomplished that they desired to have the terms in this matter of electric lighting less stringent.

The Bill was read a second time.

LEGAL INTELLIGENCE.

THE FAURE ELECTRIC ACCUMULATOR COMPANY (LIMITED) v. PHILIPPART.

This case (says the *Times*) had arisen out of the affairs of the Faure Electric Company, and it raised many important questions of joint stock company law. The company was formed in 1882 for the purpose of carrying out an agreement between M. Faure and "La Force et la Lumière," a *société anonyme* formed in Belgium, and represented by M. Philippart and others, to carry out electric lighting in that country. The Faure Company were to acquire the patented invention of M. Faure from him and the Belgian Company—which had become a mere possessor of it—and then to work it with new capital. M. Philippart held 22,000 shares, and he and others 2,000 more, on which calls were made, and then, in January, 1883, there was an arrangement which, it was said, on behalf of the Company, was a forfeiture of his shares, reserving the Company's right to calls then arising which, as they contended, meant calls made, whereas he insisted that it meant calls payable before the forfeiture. In July, 1884 the Company went into liquidation, and on the 30th of April, 1887, the liquidator, in the name of the Company, brought this action to recover the calls. These calls amounted with interest to £70,459, and the action was to recover that amount. The calls claimed were: The first call of £1 per share on 22,537 shares, made in November, 1882, and payable on December 6 and interest at 10 per cent. according to the articles of association) down to date of action, amounting altogether to £9,907, a second call of £1 per share made December 19, 1882, and payable in January, 1883, with the interest to date of action, amounting to £9,753, to first call of £1 per share on 2,000 ordinary shares of £10, standing in the joint names of the defendant and two other persons, and forfeited, as contended by the Company, on the 3rd of January, 1883, £2,000 interest thereon up to April, 1887, £879; to second call on the 2,000 shares, December 19, 1882, £2,000; to interest thereon, £854 14s. total, £70,459 14s. The defence set up was a demand that at the time of forfeiture any calls were owing, and in the alternative that if the defendant held the shares, as alleged, he held them as trustee for the Belgian Company, incorporated in Belgium and called "La Force et la Lumière;" that it was agreed between the English company, the Belgian company, and the defendant that the shares should be forfeited only upon the terms that neither the defendant nor the Belgian company should be liable for any calls upon the shares, and that accordingly, at a Board meeting of the directors of the English company on the 26th of June, 1883, a resolution was passed that it was not intended at the time of the forfeiture that the liability for past calls should continue to attach, as the forfeiture was for the common profit of the shareholders, and that the sum of £2 per share paid in the books of the company as due on the shares be transferred from capital account to the credit of the shareholders concerned—that is, Messrs Philippart; and that, in short, an arrangement was made to the effect that neither the Belgian company nor the Messrs Philippart should be liable for these calls. And it was alleged that the terms of arrangement were contained in an agreement of January 7, 1883 between the French Electrical Power Storage Company, the English company (now plaintiffs), and the Société la Force et la Lumière and the defendant. The action was by the liquidator of the company.

Mr. Channell, Q.C., and Mr. Grosvenor Woods were for the plaintiff company; Mr. Finlay, Q.C., Mr. J. Henderson, and Mr. Merrick were for the defendant.

The great point in the case was whether shares can be forfeited for non-payment of calls before the calls are payable by the terms of the resolution making the calls. The company relied on a decision of Lord Romilly (Master of the Rolls) that a call is made from the day on which it is made, although it is payable on a future day ("In re The Great Steamship Company," 38 L. J., Chancery, 512). Formal proof was given on the part of the plaintiff company that the calls were duly made; but then it appeared from the dates as to one of them that the call, though made before the forfeiture, was payable afterwards. As regarded the interest—10 per cent.—it was contended on the part of the company that upon forfeiture the interest should be "reverted," but on the part of the defendant it was contended that this only applied to the interest due at the time of the forfeiture, and that no interest due under the articles could accrue afterwards. Stocken's case, "Law Reports" 3, Chan. Appends 41, so that a claim for continuing interest at 10 per cent. due to the forfeiture, to the amount of nearly £20,000, was wholly successful. Then there was a point as to one of the calls with respect to the quorum it being contended that there was no quorum at the meeting of directors which made the calls, there being only two directors present, whereas by the articles there ought, it was said, to be three (Buckley's "Joint Stock Companies Law," 189). As stated under article 69, "the Board of Directors shall consist of not less than three directors." It shall, nevertheless, be lawful to increase the number of directors to diminish the number of directors by resolution of a general meeting on the recommendation of the board. Rule 78.—"The directors may meet together for the despatch of business, adjourn and regulate their meetings and otherwise as they think fit, and determine the quorum necessary to form a Board for the transaction of business; and until otherwise determined three shall be a quorum." On April 26, 1882, there was a resolution that two should form a quorum, and upon these rules and the resolution the question as to the validity of one of the calls depended. Upon this point the Company relied on the case of the Scottish Petroleum Company (25 Ch. Div., 412), Chancery Division; Buckley, p. 422, which held that where the articles contain one clause as to the shares, and there has been a Board of the minimum number, but by casual vacancies it has fallen below the minimum, a

quorum of the continuing directors may act, though it would be otherwise if the continuing directors were less than a quorum. But on the part of the defendant it was denied that this case was applicable, as it related to the allotment of shares. On the main question as to the alleged arrangement it was contended on the part of the Company that this could not be done, as it would be in effect a purchase back by the company of their own shares, and giving up a part of their called-up capital ("Trevor v. White," 12, Appeal Cases). The other points were also controverted, and the case was argued at length on these questions by Mr. Channell and Mr. Finlay, after which the learned Judge took time to consider his judgment, which, on the 27th inst., was given as follows:

Mr. Justice Hawkins: The plaintiff company was duly incorporated on Feb. 15th, 1882. Its nominal capital was £1,000,000, divided into 80,000 ordinary shares of £10 each, and 200,000 deferred shares of £1 each. The defendant at the time of making the calls hereafter mentioned was the holder of 22,532 ordinary shares standing in his own name, and of 2,000 like shares standing in his own name with two others, making a total of 24,532 ordinary shares, upon each of which £2 had been paid. On November 7th, 1882 a call of £1 per share was made, payable on December 6th. On December 19th a further call of £1 per share was made, payable on January 20th, 1883. To recover these calls, with interest at the rate of 10 per cent. from the dates upon which they were payable up to the present time under Article 24, this action was brought. On January 3, 1883, by resolution of the board of directors, constituted as hereafter mentioned, the whole of these shares were declared forfeited for the non-payment of the first call under Article 39. The defendant himself was a member of this board, presided at it, and assisted to pass the resolution. No objection was raised as to the validity of the first call. Indeed, having regard to the resolution, no such objection could be raised. The second call, however, was objected to by the defendant on the grounds, first, that it was not legally made, and, secondly, that if it were it was not "owing" within the meaning of Article 39 at the time of the forfeiture. The first of these objections was based upon three grounds. By Article 69 "the board of directors shall consist of not less than three nor more than seven." By Article 78 the directors have power to determine the quorum necessary to form a board meeting for the transaction of business, and "until otherwise determined three shall be a quorum." By a resolution of the directors passed on April 26, 1882, the number of a quorum was reduced to two. Before December 19, 1882 (when the second call was made), by the resignation of some of the directors originally appointed the board was reduced to two, the defendant being one and a Mr. Calvert the other. These two were sufficient to form a quorum, but were not sufficient to form a board for the purposes of transacting the business of the company upon December 19. At that meeting the defendant was voted to the chair; they then, as the first act of business, proposed a resolution that the board should increase itself to five members, and they proceeded to nominate three other gentlemen as directors, who immediately accepted the office, and thus the board was increased to five, and at once proceeded to pass the resolution for the second call. It was urged for the defendant that until the board was increased to three members at least the two gentlemen, though sufficient to form a quorum of a properly constituted board, had no power to act, either by increasing the number of directors or making a call. As between the company and the general body of the shareholders, who were no party to the resolution, I think these objections would be fatal. By Article 22 calls are to be made by "the Board of Directors," and if there be no valid board it is difficult to see how there can be a quorum of the board. The word quorum in its ordinary sense has reference to the existence of a completed body of persons, of whom a certain specified number are competent to transact the business of the whole. But a quorum of a board of directors does not constitute the board, though in the absence of other existing directors it may legally transact all such business as the whole board is competent to transact. Nothing could illustrate this proposition better than the articles of the plaintiff company, which require a minimum of three directors to form a board, though two may constitute a quorum of the board when formed. The case of the Scottish Petroleum Company (25 Ch. Div., 412) does not militate against this view, for although in that case it was held that a quorum of two directors of a board which was not filled up to its minimum number might make an allotment of shares, it was held so, not because the quorum was equal to a duly constituted board but because of a provision in the company's articles to the effect that in the event of a casual vacancy occurring in the board of directors, the continuing directors might act, notwithstanding such vacancy. In the articles of the plaintiff company I find no such special provision, and thus the two cases are distinguishable. It was said, however, on behalf of the plaintiff company that in their case before the call was made the board was made up to more than its minimum number by the appointment of the three additional directors. This brings me to the question as to whether the two directors who alone represented the plaintiff company at the commencement of the board meeting at which that increase took place were competent to add to their number, and fill up the vacancies so as to constitute a valid board. I am of opinion that they were not. By Article 73, it is provided that "Any casual vacancy occurring in the office of director before the ordinary general meeting in 1885 may be filled up by the board of directors appointing some qualified member thereto." Admitting that the vacancies were "casual vacancies," I fail to understand how a "casual vacancy," which can only be filled up by the board, can be filled up if no properly constituted board is in existence at the time. It may, I know, be argued that this difficulty is surmounted by the latter part of Article 78, which provides that "the directors assembled at a board meeting duly summoned may, if a quorum is formed, exercise all the powers of a board of directors, notwithstanding any vacancy in the number of directors." The very words of this article imply, his Lordship continued, that there must be at the time an existing board to be summoned, though there may be a vacancy in its full number, as ordi-

narily composed. It seems to me that the true meaning of that article is, that if the numbers of the existing legally constituted board are duly summoned, but a quorum only attends, the quorum may exercise the powers of a board. This, however, is far from saying that two directors may constitute a board, which the articles require to be composed of three at least. I am aware that dicta are to be found in the case of "The York Tramway Company v. Willows" (8 Q.B.D., 685), which may be cited as imitating apparently against this view. It is to be observed, however, that those dicta had reference to articles differing from the present ones, and, moreover, they were not essential to the decision of that case. It was urged that the business would come to a standstill unless the two continuing directors were able to appoint another to make a valid board for the transaction of the business. It may be that the business would be at a standstill until a complete board was formed; but that argument of inconvenience is not sufficient to confer upon two directors only the powers of a Board which the very constitution of the company says shall not consist of less than three. I cannot regard the objections I have discussed as other than serious and substantial ones. The subscribers to the company have, by the articles of association, a right to have the benefit of the judgment of, and to have their affairs transacted by, a board of three directors at least, and I can conceive for matters of business nothing more important than the selection and appointment of the directors to whom the affairs and management of the company are to be intrusted, and whose integrity and action may make all the difference between success and insolvency. When, therefore, a company's articles provide for the filling up of a vacancy by the board, I think it means a properly constituted board, and not merely two directors, as here, who do not and cannot form a board. This question was, his Lordship said, fully dealt with in *"In re Albion Spinning Company—Bottomley's case"* (16 "L.R." Ch. D., 661). Continuing, he said,—"There is, however, a ground upon which, I think, the liability of the defendant may be sustained, notwithstanding the objections I have mentioned and discussed. The defendant, as a director, was in the chair and assisted to pass the resolution to fill up the vacancies in the board. He, with his other colleagues, passed the resolution for the call under discussion, and also for another call payable on February 19, directed notices of forfeiture to be issued to members who had not paid the first call, and passed a resolution for an interim dividend, and at the next meeting on January 3, 1883, the minutes of the previous meeting were read over and signed by the defendant as chairman. At the meeting of January 3, the defendant being in the chair, resolutions were passed forfeiting shares for the non-payment of the first call, including those held by the defendant himself in respect of which the calls were made. Having regard to these facts, I think the defendant is estopped from disputing the validity of the call in question. I do not think it necessary upon this point to do more than refer to the judgment of the present Master of the Rolls in *"The York Tramways Company v. Willows"* (*supra*, page 699). The next question raised by the defendant was whether the second call, which was made before (but the day for payment of which had not arrived when) the resolution of forfeiture was passed, could be said to be owing at the time of such forfeiture. Article 39 provides that "any member whose shares have been declared forfeited shall notwithstanding be liable to pay to the Company all calls owing upon such shares at the time of the forfeiture, and the interest (if any) thereon." The defendant contended that, inasmuch as the second call, made on December 19, 1882, was not payable until January 20, 1883, it could not be said to be owing when the shares were declared forfeited on January 3, 1883. Independently of authority, I should have been of opinion that immediately after the call was made it was owing, according to the true construction of the article, though payment of it could not be legally enforced till a month afterwards. The judgment of Lord Romilly in *"The China Steamship, &c., Coal Company, Davies's case"* (38 L.J., Ch., 512), however, is in point in support of this view. As regarded the claim for interest, it was contended for the defendant that the 24th article, which makes a member liable to pay interest upon his unpaid calls, from the day appointed for their payment to the time of actual payment, at 10 per cent. per annum, was no longer obligatory, upon the defendant's ceasing to be a member, by the forfeiture of all his shares; and that after such forfeiture no interest could be claimed—and certainly none could accrue after the forfeiture; and, further, that even if any interest could be recovered in respect of calls remaining unpaid after the forfeiture, it could not be at the rate of 10 per cent., but only under (3 and 4 Will. IV., cap. 42, sec. 28; in support of which, *"In re Blakeley Ordnance Company, Stocken's case"* (5 "L.R." Eq., 6, and 3 "L.R." Ch. App., 412), was, his Lordship said, cited. Having referred to the judgment in that case, his Lordship continued:—"It is unnecessary to inquire at length into the considerations upon which it was decided, which are fully given in the judgments of Lord Cairns and Romilly. But for the words in the 39th article of the plaintiff company, 'and the interest (if any) thereon,' this case (Stocken's) would have been conclusive in favour of the defendant's contention. Those words, however, in my opinion, create a right in the plaintiff Company to interest at the rate of the 10 per cent. named in Article 24 up to the time of the forfeiture upon the first call, which had previously become payable, but not upon the second call, the time for payment of which had not then arrived. I think that the true construction of the 39th article was to reserve to the plaintiff Company all such rights as they might have against a defaulting shareholder up to the date of the forfeiture of his shares, and to confer upon them the power to enforce such rights by an action, notwithstanding the extinction by Article 40 of all rights incident to the forfeited shares. As regarded the interest claimed to have accrued after the forfeiture, his Lordship said he was clear, on the authority of Stocken's case (*supra*), that none could be claimed either under Article 24 or under the statute, because no demand of payment was ever made after the forfeiture, when the new right so sought to be enforced had

arisen. The result was that interest could only be allowed upon the first call at the rate of 10 per cent. up to January 3, 1883, when the shares were forfeited and that all other interest would be disallowed. As regarded the defence set up that it was agreed between the plaintiffs and the defendant and the Belgian Company that the shares should be forfeited only upon the terms that the liability of the defendant to pay calls in arrear should cease, his Lordship held that there was no evidence to support any such agreement. He further said that, even had such an agreement been proved, in his opinion it would have been invalid, because the board had no power to enter into any such agreement. As to the defence that, assuming the defendant had been liable to the plaintiff Company, as alleged, his liability had been discharged by bankruptcy proceedings in France, the learned Judge held that this was not proved in evidence, and that even if it had been it would have afforded no defence. (*supra* "Barley v. Hedges," 1 "B. and S." 375). In conclusion the learned Judge said:—"In my opinion, the defendant has established no legal answer to the plaintiffs' claim for the unpaid calls, but has to a large portion of the claim for interest. My judgment, therefore, is for the plaintiff company for the full amount of those calls, amounting in the whole to the sum of £49,064, together with interest upon £24,532, the amount of the first call, at 10 per cent. per annum from December 6, 1882, when that call became payable, up to January 3, 1883, the date of the forfeiture, amounting to £204—say £204—making a total of £49,268.

COMPANIES' MEETINGS.

THE ANGLO-AMERICAN BRUSH ELECTRIC LIGHT CORPORATION.

The seventh ordinary general meeting of the Anglo-American Brush Electric Light Corporation (Limited) was held on Friday last at the City Terminus Hotel.

Lord Thurlow, F.R.S., presided, and, in moving the adoption of the report, said they had now worked at a profit during the whole of 1886 and 1887. The volume of their business in the past year had increased, compared with that of 1886 by 23 per cent., and by the economies they had been enabled to introduce during the same time their net profits had increased by nearly 10 per cent. That, he thought, was a very favourable statement of affairs taken by itself, but it was still more satisfactory when it was considered by the side of the great fall that had taken place in the prices of all electrical appliances. In illustration of the great fall of prices, which had considerably increased the difficulties of the Company, he might mention that in 1886 the largest class of Brush dynamo made by them cost £800, whereas they were now making a machine more efficient, more powerful, and superior in every way for £360. With the aid of their very efficient staff, they had been enabled to counterbalance that depreciation. Besides the economies effected by the business being now all under one roof, by their having made advantageous contracts for coal, oil, and other supplies, and by the reclassification of rates for the conveyance of electrical machinery to which the railway companies had agreed. They had acquired their Austrian business through having absorbed on favourable terms the undertaking of the International Electric Company. The assets taken over consisted, broadly speaking, of two things—the street lighting installation at Temesvar, in Hungary, and the large share held by the International Company in the firm of Krenn, Mayer, and Co., electrical engineers and manufacturers, in Vienna. Temesvar consisted really of three towns joined together and the district was entirely lighted by electricity, and had been so lighted for some years. The mains were over 30 miles in length. The lighting, which was effected by 700 incandescent lamps, was exclusively by the Brush system. The contract was for 25 years, at the expiration of which the municipality could either renew the contract or purchase the installation at a very fair valuation. The lighting was now being done at a small profit, and the private lighting along the 30 miles of streets was almost daily increasing. Since assuming the undertaking of the International Company they had acquired the remaining portion of the business of Krenn, Mayer and Company. Since the publication of the report, the accounts of the firm for the past year had come to hand, and they showed a profit. They had been generally commended for the way in which they had carried out the contract for lighting the Jubilee Exhibition at Manchester last year. That was the largest piece of arc lighting ever done in England, 600 lamps being used. They had now undertaken a similar piece of work for the Glasgow Exhibition, for which, however, 400 lamps would be required. After what had occurred in the past year they considered that they had established their position in Great Britain. In regard to the patent for compound winding of dynamos, no machine could be made in future on that principle without the Company receiving a royalty. Only one firm had contested their rights; but if the case came into Court they had no doubt about being able to establish their claim. They were now making an alternate current machine under an entirely new design. They had also patented and were adopting a new type of transformer for transforming high tension into low tension current, and also *arc*. He hoped the shareholders would approve as they would do by adopting the report the bonus scheme for admitting the principal officers and the heads of departments to a participation in the profits made by the Company. The patents now stood in the balance sheet at £57,674, and knowing what those figures covered he considered the item an eminently satisfactory one. They owed trading people at the end of the year £12,341, or £600 less than their indebtedness a year previously, while the amount owing to the Company on the 31st December was £45,600, or 50 per cent. more than was due to them a year ago. The negotiations with the Commissioners of

Suitors had been pending for several years. The contract would only give them a fair tradesman's profit, but indirectly it would benefit the Company immensely. He believed they would be able to bring the authorities of the South-Eastern Railway Company to a sense of the justice of the demands made by the Corporation for reasonable compensation for any inconvenience which the railway company might put them to in connection with the acquisition of their premises at Belvedere-road. In regard to the litigation with the Edison and Swan Company, they were convinced that they had a good case, and that view was supported by their legal and technical advisers. He strongly urged every one who was interested in electric lighting to read the chapter on the early history of the gas industry in Mr. Burlett's "Official Intelligence" for 1888, in which reference was made to the enormous amount of capital sunk at the outset in that industry, and to the fact that it took 25 years before gas could be worked at a profit. Not a quarter of the money that was lost, sunk, or thrown away in the early history of the gas industry had been lost, sunk, or thrown away in introducing the electric light, and as to its taking twenty-five years to make the electric light pay, he did not like to prophesy, but he would venture to say that twelve years from the introduction of the scheme in 1880 there would not be a gas lamp in the streets of any town in England. The Bill introduced by him into the House of Lords last year, which could not then, owing to various difficulties, be proceeded with in the House of Commons, had been reintroduced into the House of Lords this year. He had received the assurance of the support of the Government, and he thought there was every reasonable prospect of the Bill becoming law.

Mr. J. Scudamore Sillon seconded the motion.

In reply to a question, the Chairman stated that the reason he laid so much stress on the street lighting was because he felt that by that means they would be enabled to get the electric light into private houses.

The report was unanimously adopted, and the retiring directors and auditors were re-elected.

TELEPHONE COMPANY OF EGYPT.

The annual general meeting of the Telephone Company of Egypt (Limited) was held on Tuesday at the offices, Austinians, General Alexander Fraser, C.B., presiding.

The Chairman said he thought the shareholders might regard the present position of the company as satisfactory. For the past year they had again proposed to pay 6 per cent.; and after writing off a considerable sum for depreciation they would carry forward an amount equal to about 1 per cent. more on the preference capital. Their gross business had increased by quite 50 per cent. since they started, but the working expenses had not grown by anything like the same proportion for their economical working they were greatly indebted to their late manager, Mr. A. D. Evans, whose death they very much regretted, and whose son, Mr. W. N. Evans, they had elected to the position, since the issue of their report the extension of their business to Helwan, about 16 miles from Cairo, had been completed, and they expected a large business from that connection. After consulting the principal shareholders, the board had decided to ask the present meeting to pass a resolution extending the borrowing powers of the Company from £5,000 to £20,000. They suggested that there should be a present issue of £10,000 only, of which a portion would be required to pay off a loan, and the remainder would represent working capital. Including that loan, they had spent about £10,000 in new constructions over and above the capital issued for acquiring the business as a going concern. He thought they would have no difficulty in placing their debentures at 6 per cent. He concluded by moving the adoption of the report and the payment of a dividend of 6 per cent. on the preferred shares.

Mr. Henry Crewing seconded the motion, which was unanimously accepted.

A resolution was afterwards passed authorizing the directors to issue debentures to an amount not exceeding £20,000.

PROVISIONAL PATENTS, 1888.

FEBRUARY 24.

- 772. Improvements in electrical safety appliances. Killingworth William Hedges, 8, Quality-court, London, W.C.
- 784. A method of and apparatus for electrically lighting railway and other carriages. John Inray, 28, Southampton-buildings, Chancery-lane, W.C. (Robert Inray, South Australia.)
- 785. Improvements in holders for electric glow lamps. Edward Frederick Hermann Heinrich Lockert, 28, Southampton-buildings, Chancery-lane, London, W.C.
- 794. Improvements in electrical firing keys or contact makers. Charles Andrew McEay. The London Ordnance Works, Bear lane, Southwark, Surrey.

FEBRUARY 25.

- 2808. Electro-magnetic conductors for electric and magnetic machines, induction coils, transformers, &c. Henry Francis Joel, 44, Lavender-grove, Duxton, London.
- 2819. Improvements in electrical measuring instruments. Francis Henry Nalder, Herbert Nalder, Charles William Scott Crawley, and Henry John Payne, 132, Horseferry-road, Westminster S.W.

FEBRUARY 27.

- 2876. Improvements in the method and means of working the driving appliances on electrically propelled vehicles. Michael Kaskellic Ward, 55, Chancery-lane, London, W.C.
- 2883. Lighting a lamp from the incandescent wire of a galvanic battery. Henry Ferdinand Richardson, Oakland, Waldegrave-road, Teddington.
- 2933. Improvements in mechanism for regulating the force of dynamo or magneto-electric generators. Herbert John Hadlan, 18, Buckingham-street, London. (Warren Samuel Hill, United States.)

FEBRUARY 28.

- 2956. Automatic electrical "fog-signalling" on railways working in conjunction with the present block system. Arthur Butler Harris, Trinity College, Oxford.
- 2968. The production of musical tones directly by electricity, and the application thereof. John Eschby and Edwin Eschby, 5, Eden Quay, Dublin.

FEBRUARY 29.

- 3041. An apparatus for attaching to automatic delivering machines, for regulating and governing any required time for lighting or igniting cigars and cigarettes by electricity. Edward Elgar Atkins, 9, Villa Grove, Hantsworth, near Birmingham.
- 3072. Improvements in automatic electric induction apparatus. Henry William Rhoads and Frederick William Ticehurst, 8, Quality-court, London.
- 3075. An improved clutch for regulating feeding rods in electric arc lamps. Alfred William Southey, 1, Cullum-street, City.
- 3097. An improvement in holding the plates of secondary voltaic batteries. Bernard Mervyn Drake and John Marshall Goham, 28, Southampton-buildings, Chancery-lane, London, W.C. (Complete specification.)

MARCH 1.

- 3146. The manufacture of a new non-magnetic alloy. Heinrich Ostermann and Charles Lacroix, 68, Fleet-street, London.
- 3149. Improvements in galvanic batteries. Louis Kayser, 23 Southampton-buildings, Molesley.

COMPLETE SPECIFICATIONS ACCEPTED.

MARCH 21, 1887.

- 4225. Improvements in electricity meters, parts of which improvements are applicable to dynamo-electric generators and motors. George Hookham, 7, Staple Inn, Middlesex.

APRIL 16, 1887.

- 5662. A system of generating, reproducing, and distributing electricity. William Maxwell, 54, Claybrook-road, Fulham, S.W.

APRIL 19, 1887.

- 5709. Improvements in dynamo-electric machines. Alphonse Ignace Gratier, 6, Bream's-buildings, London, E.C.

APRIL 22, 1887.

- 5867. Improvements in secondary batteries. William Kingland, 49, Cambridge-road, Gunnersbury, W.

APRIL 27, 1887.

- 6168. Improvements in or connected with telephones for checking payment for the use of the telephones. Hubert Padden Jackson, 47, Lincoln Inn fields, London, W.C.

APRIL 29, 1887.

- 6294. Improvements in the electrolytic treatment of zinc and its ores. Alexander Watt, 6, Bream's-buildings, E.C.

DECEMBER 23, 1887.

- 17,704. An improvement in telephones. Abram Charles Herts, 33, Southampton-buildings, Holborn, London.

SPECIFICATIONS PUBLISHED.

1887.

- 3046. Registering, &c., earthquakes, &c. T. Gray. (Milne. 11d.)
- 3658. Alternating current transformers. R. Dick and R. Kennedy. 8d.
- 4781. Electric batteries. The Electrical Power Storage Co. and W. H. Butler. 6d.
- 4809. Insulating electrical conductors. E. Tortora. 8d.
- 17,837. Generating electricity from heat. P. M. Justice. (Johnson. 8d.)
- 17,888. Electro-magnetic marine governors. G. A. Smith. 6d.

NOTICE.

The Notices hitherto sent by the Office to Applicants for Patents, reminding them of the date for filing a Complete Specification, will not in future be issued.

CITY NOTES.

Brazilian Submarine Company. The traffic receipts of the Brazilian Submarine Telegraph Company, Limited, for the week ending March 2 amounted to £4,435.

Armstrong's Electric Light Company. Captain C. D. Inghs R. N. resigned his seat on the board of the Armstrong's Electric Light and Power Company, Limited, on February 23.

West Coast of America Telegraph Company.—The traffic receipts of the West Coast of America Telegraph Company (Limited), for the month of February were £4,625.

Great Northern Telegraph Company.—The receipts of the Great Northern Telegraph Company for February, 1888, amounted to £20,400, and from January 1 to February 29, to £41,800 against £39,600 for the corresponding two months in 1887.

New Company. The Electrical Works Construction and Maintenance Limited. Registered by George Amnestey Grindle, 19, Great Winchester-street, with a capital of £2,000 in £1 shares. Object, to carry on the business of electricians and electrical engineers.

Western and Brazilian Company. The traffic receipts of the Western and Brazilian Telegraph Company (Limited), for the week ending March 2 after deducting the fifth of the gross receipts payable to the London Platino Brazilian Telegraph Company, were £3,766.

German Union Telegraph Company.—The directors of the German Union Telegraph Company have declared a final dividend of 8s. 3d. per share free of income tax for the year 1887, making the total distribution 14s. per share, or at the rate of 7 per cent. per annum.

Direct Spanish Telegraph Company. The estimated traffic receipts of the Direct Spanish Telegraph Company Limited for the month of February amounted to £1,858, against £1,623 for the corresponding period of last year.

West India and Panama Telegraph Company.—The estimated traffic receipts of the West India and Panama Telegraph Company (Limited) for the half-month ended Feb. 29 were £3,139, as compared with £2,840 in the corresponding period of 1887. The November receipts, estimated at £5,236, realised £5,314.

Electrical Companies Registered in February:—

Homes to Homes Electric Light Supply, in £5 shares	£350,000
Machinists' Electric Automatic Registering Co., in £1 shares	20,000
Notting Hill Electric Lighting, in £1 shares	100,000
Northampton Electric Light and Power, in £5 shares	4,000
Gulcher New Electric Light and Power Co., in £1 shares	70,000
Electrical Automatic Delivery Box, in £1 shares	60,000
Institute of Medical Electricity, in £1 shares	20,000
Eclipse Electric Lighting Syndicate, in £1 shares	20,000
Electric Traction, in £10 shares	30,000
Series Electrical Traction Syndicate, in £1 shares	30,000

Showing a total capital required of £704,000

German Union Company.—The report of the directors of the German Union Telegraph and Trust Company (Limited) for the 12 months ending December 31, 1887, states that the total receipts during the 12 months amount to £15,368, which, with a balance of £51 brought forward from last account, make a total of £15,369. The expenses for the same period amount to £892, of this sum £750 is provided by the German Union Company of Berlin. Out of the receipts an interim dividend of 5s. 9d. per share was distributed on January 17 last, and the directors recommend the payment of a further dividend of 8s. 3d. per share, making a total distribution for the year of 14s. per share free of income tax, or at the rate of £7 percent per annum (as against £6 paid last year, leaving a balance of £156 3s. 5d. to be carried over to next account. The proposal of the Imperial German Government for the acquisition of the cables and property of the Berlin Company has been accepted, and an agreement on the terms sanctioned by the extraordinary general meeting of this Company of November 28, 1887 has been entered into, subject to the formal approval of the Reichstag which is daily expected. The result of the agreement will be so far as can at present be foreseen that the Berlin Company will begin to go into liquidation in April next, and that the shareholders of this Company will receive a return in respect of their capital early in 1889, when the Government will pay the purchase money. The exact sum to be paid to the shareholders of this Company cannot be determined at present, but it will probably be about par that is about £10 per share, less expenses of liquidation, which will make a fractional reduction.

New Thermo-electric Couple.—Any progress bearing upon the question of the direct conversion of heat energy into electrical work is of interest to a considerable section of our readers. We therefore—although the details of the discovery are not yet forthcoming—notice the statement made by some of our foreign contemporaries that a new thermo-electric couple having an E.M.F. as high as 0.18 volt, and a resistance as low as 0.009 ohm, has been constructed by M. Heimeel. The importance of these figures becomes evident when it is pointed out that the thermo-electric couple best known in this country, that of Clamond, has an E.M.F. of only 0.02 volt with a resistance of 0.02 ohm.

Barcelona Exhibition.—At the request of the Secretary of State for Foreign Affairs, the Society of Arts has undertaken to promote the interests of the Exhibition in this country, and to act as the intermediary between British exhibitors and the Executive of the Exhibition. The Exhibition is announced to be opened on the 9th April, and the date for the receipt of applications from foreign exhibitors has already passed. A request for an extension of the time has been made to the Spanish Executive. In the meantime, British manufacturers who wish to take part in the Exhibition, and have not already sent in applications for space, may apply to the secretary of the Society of Arts, John-street, Adelphi, W.C.

Electric Lighting at Glossop.—Mr. Herbert Rhodes, in reply to a statement made at the last meeting of the Council, during the discussion on the purchase of the gas-works, with reference to the adoption of the electric light at some of the local mills, said the firm he represented put 1,400 electric lamps into their mills in 1886; and these gave so much satisfaction that in 1887 they put in another 1,000. Two other local manufacturers had adopted the electric light; and though corporations ought to own gas and water works, he considered that under these circumstances it would be the height of folly to entertain the idea of purchasing the gas works. The Mayor (Alderman Sidebottom) said he quite agreed with these remarks.

Taunton. The Lighting Committee of the Town Council have resolved to recommend the Council to provide 30 additional arc lamps for public lighting of the streets of Taunton, and they have suggested where these lamps should be placed. The limits are Haines-hill on one side, the Laurels, Staplegrove; the corner of Wellington-road, the bottom of East-reach, the end of Silver street and Mountlands, and the corner of the roadway near the Railway Station. It is proposed to place a lamp opposite St. George's Church, one at the junction of the roads near the Compass Inn, one in Castle Green, one near the Convent, and one at the junction of the Staplegrove-road and Nursery Estate roadway. The Committee consider that 30 lamps will be quite sufficient to light the principal outlying streets.

Kensington.—At the last meeting of the Kensington Vestry a letter was read from the secretary *pro tem.* of the Notting-hill Electric Lighting Company, inquiring whether it is probable that the Vestry will shortly notify their assent to the undertaking of that company, as they feel sure that not only their undertaking, but the residents in the district generally, will be prejudiced by delay. A letter was also read from the Kensington Court Electric Lighting Company, calling attention to the serious prejudice caused to the company by the delay in dealing with their application for powers to lay underground mains

through an extended area in this parish, and asking that the approval of the Vestry may be notified with the least possible delay, especially as the whole question has still to be reviewed by the Board of Trade. Both communications were referred to the Electric Lighting Committee.

Austria. The utilization of the electrical works at Salzburg was recently initiated with 300 incandescence and 26 arc lamps. The installation, carried out by the branch establishment at Vienna of the firm of Siemens, comprises two horizontal tubular boilers, two steam engines of 100 h. p., and three dynamos. The price per hour per incandescence lamp is four kreuzers (9.2 centimes).—At Gorlitz, the establishment of a central station for electric lighting is under consideration. Messrs. Siemens, of Berlin, have submitted a plan which, for an installation of 4,500 incandescence lamps, involves 500 steam h. p., and an expenditure of 625,000*fl.*—The firm of Ganz and Co., of Budapesth, has recently introduced the electric light in several theatres, notably in those of Riga and Odessa. In the case of the latter town, the central station supplying the theatre is at a distance from it of about 14 kilometres.

Royal Meteorological Society.—At the ordinary meeting of the society, to be held by kind permission of the Council of the Institution of Civil Engineers, at 25, Great George-street, Westminster, on Wednesday, the 21st instant, at 7 p.m., an address will be delivered by the President, Dr. W. Marcet, M.D., F.R.S., on "Atmospheric Electricity," illustrated by experiments; after which Mr. G. J. Symons, F.R.S., will make a short communication on "The non-existence of Thunderbolts;" elucidated by accounts of searches after them and the exhibition of specimens. The meeting will then be adjourned, in order to afford the fellows and their friends an opportunity of inspecting the exhibition of apparatus connected with atmospheric electricity, including lightning conductors, photographs of lightning and damaged objects, and of such new instruments as have been invented and first constructed since the last exhibition.

Safety in Theatres.—Some interesting experiments to test the degree of security from fire afforded by the use of incandescence lamps were recently carried out by the Paris superior Committee on Theatres at the central laboratory of electricity at Grenelle, under the direction of M. Mascart. The lamps were successively applied to, and crushed to pieces in contact with, portions of scenery canvas, gauze, velvet, &c., but without any scorching or other appreciable effects. The most conclusive experiment was made with a piece of canvas which had been in use for ten years, and which was reduced to the condition of tinder by the heat of the gas lights. It was placed in direct contact with a 50 c.p. Swan lamp for upwards of an hour, without producing any signs of combustion, scorching, or smoke. The Committee will shortly carry out another series of experiments before definitively deciding the question as to the absolute safety of a properly-devised installation of incandescence lighting.

Telephone Exchange for Godalming.—A meeting of the inhabitants of Godalming was held in the Masonic Hall, Godalming, on Tuesday, the 6th inst., to consider the proposal of the Equitable Telephone Association to establish a telephone exchange in Godalming and district. The Mayor (Alderman Stedman), in the unavoidable absence of the vicar (the Hon. and Rev. Canon Brodrick), presided, and after the meeting had been addressed by Mr. A. A. Campbell Swinton and Mr. Macpherson Grant, of the Equitable Telephone Association,

the following resolution was moved by Mr. E. Pullman, of Godalming, and on being seconded by Mr. E. Stollman, was put to the meeting and declared by the chairman to be carried *unanimously*:—"That this meeting considers it, in order to keep with the times, desirable to establish a telephone exchange in Godalming, if a sufficient number of subscribers can be enlisted." The Swinton telephone instruments were fitted up for the occasion in connection with the hall, so that before they dispersed the visitors had an opportunity of testing them practically.

The Strike at Chelmsford.—Inasmuch as the mere mention of a strike frequently leads to mistaken opinion, we have endeavoured to obtain the real facts of the recent strike at Messrs. Crompton and Co.'s works, at Chelmsford. It appears that, by the command of the Union, men are not permitted to do piecework. A deputation from the men waited on the heads of the firm to explain their position in regard to the work and the Union. It is the intention of the Union not to allow piecework to be introduced into any of the new trades. Under these circumstances, Messrs. Crompton and Co. and the men agree to differ, and to part. The affair is simply and purely a question of "Union rules." The number of men employed by Messrs. Crompton belonging to the Union was very few, and there will be no difficulty in replacing them by non-Union men, nor will the firm suffer any inconvenience because of the defection. We are sorry that there should be imparted between masters and men any differences of opinion, but in these days of keen competition it is absolutely necessary that the masters should have the sole control of their shops.

Berlin Telegraphy.—Friday last will long be remembered as the busiest day on record at the Central Telegraph Office of Berlin. The pressure was great on Thursday, when 29,878 telegrams, aggregating 799,926 words, had to be sent off. But this record was eclipsed by the following day, no fewer than 36,615 telegrams, containing together 1,115,551 words, being despatched to all parts of the globe, and in different languages. All the Government telegraphists fit for duty had to be called in to meet the pressure, and all the available instruments were worked. It was a fortunate circumstance that the Berlin Bourse was closed, as this enabled the authorities to make use of the instruments there for the work. During the busiest hours of Friday last no fewer than 346 telegraphists were at work at the same time in the great instrument room of the Central Telegraph Office, and 230 instruments were operated. The above figures are startlingly high, no doubt, for Berlin; but would not be considered very wonderful at the central station of our G.P.O., where on one occasion the day before the Jubilee day (June 20, 1887) the total number of messages dealt with was no less than 124,291.

Bath. Last week, at the Council Meeting, upon a proposition being made that the chandeliers in the Banqueting Room at the Guildhall should be repaired, at an expense of £30, Mr. Jolly moved an amendment to the effect that no expenditure be incurred at present, but that the Borough Property Committee be instructed to obtain plans and estimates for lighting the Guildhall with the electric light, using as a motive power the water now running to waste in the river, the property of the Corporation. He fully admitted all that could be said as to the handsome character of the chandeliers, but described the inconvenience which those who are in the habit of addressing meetings at the Guildhall feel from the almost blinding effect of the chandeliers,

and also from the vitiated state into which the atmosphere quickly gets. He also suggested that sufficient power would be obtained by the means proposed to illuminate the market as well. Mr. Jolly's proposition met with the support of several members of the Council, and it would undoubtedly have been carried had it not been for the fear that the introduction of the electric light would necessarily mean the removal of the chandeliers. In the result the amendment was lost by 12 votes to 16.

Brilliant Illumination v. the Eyesight. The opponents of electric lighting are apt to insist upon the ill effects of a brilliant illumination under conditions which, it is admitted, should be carefully avoided, but they comparatively seldom refer to the still more injurious effect upon the eyesight of an insufficient and unsteady light. This question was treated at considerable length by Dr. G. Sans in a paper "On the Electric Lighting of Theatres," commenced in the second and ended in the third number of the present series. We quite endorse the following observations made by Dr. Morton at the last general meeting of the American Gaslight Association; but we fail to perceive that they have an application specially adverse to electric lighting such as has been attributed to them. "There is no doubt," said Dr. Morton, "that the present generation are risking their eyesight by the use of so many brilliant lights." He then pointed out that the eye requires a *thoroughly diffused light*, and alluded to the paralyzing effect and ultimate injury to the organs of vision produced by frequent exposures to unscreened electric and powerful gas lights. Where it was found convenient or necessary to employ very powerful lamps, they should be placed well above the ordinary visual range, and shaded so as to produce a diffused and equable light.

Society of Arts. The first of a short course of two lectures on "The Protection of Buildings from Lightning," was delivered by Prof. Oliver J. Lodge, F.R.S., on Saturday afternoon last. The lecturer began by giving a slight historical sketch of the subject, and called attention to the outstanding questions, difficulties, and points of controversy in connection with lightning conductors. He described the methods usually adopted, and showed that the reasons given for failure were often quite insufficient to account for it. An interesting experiment showed the effect of a minute quantity of electricity, and explained the reason of the large size of the raindrops in thunder showers. As soon as a stick of sealing wax rubbed on the coat sleeve was presented in the neighbourhood of the jet of a tiny fountain, the drops previously falling in spray were collected, and fell as an almost continuous stream. In conclusion, the lecturer referred to the futility of ordinary galvanometer tests for lightning rods, and argued that the behaviour of a feeble battery current afforded no analogy whatever by which to estimate the effect of the explosive and shattering lightning discharge. At the second lecture on Saturday next, experimental answers will be given to some of the questions raised, and an endeavour will be made to supply a more complete account of the liability of conductors to side flash than has yet been attempted.

Electric Lighting in France.—The Continental Edison Company has nearly completed the installation for the electric lighting of the Odeon Theatre in Paris, which is to be inaugurated on the 20th inst. It comprises 1,200 incandescence lamps, of which 1,000 are in ordinary use. There are three dynamos, each capable of working 500 lamps; the motive power for which is supplied by three Weyer

and Richmond steam engines, each of 70 h. p. The same Company has, on the occasion of the production of a new piece, added 20 Jablochhoff candles to the installation at the Galte Theatre. At Boulogne-sur-Mer they have carried out an installation at the Casino, comprising 700 incandescence and 30 arc lamps; the latter being for the illumination of the gardens. The lamps are worked by two Edison dynamos, the motive power for which is 100 h. p. The *Compagnie Française d'Eclairage Electrique* is carrying out considerable extensions at its station in the Faubourg Montmartre. It is now working over 1,700 lamps, and has signed contracts for the supply of 10,000 more. The present installation is capable of supplying 20,000 lamps. The establishment of twenty seven special telephonic lines connecting the Saint-Louis Hospital with call stations in different quarters of Paris has just been authorised by the Government. By means of this arrangement, a special conveyance for the transport of patients to the hospital may be obtained within a few minutes in any of the districts in question.

Bournemouth. Mr. W. E. Shakell, the secretary of the Bournemouth Electric Light Company, has written to the Commissioners for permission to open the roads for the purpose of laying down mains; and, at the last meeting of the Commissioners, the Roads Committee reported that they had asked for full particulars and plans as to what it was proposed to do in the matter. At the same meeting, on the recommendation of the Lighting Committee, it was resolved, in reply to a letter from Messrs. Phillips, Harrison, and Hart (offering to light the pier and pleasure grounds with electric light at costs varying according to the method adopted), to inform the writers that "the Commissioners are not prepared to entertain the matter at present." A further letter was read from the same firm, stating that they intended to apply to the Board of Trade for an electric lighting license for the district of Bournemouth, and, the clerk stating that such a license would give them power to open the roads, &c., it was resolved that the matter should be discussed at a meeting of the Commissioners on the 17th April, when they would decide whether they would consent to the proposed license. It seems that this application is very late in the day; besides it is well known that a local company, to whom Messrs. Phillips, Harrison, and Hart are altogether unknown, has been formed to carry out the lighting at Bournemouth; and in such cases, for such a purpose, a local company is far better than outsiders.

New York.—The *Daily News* correspondent telegraphs on Tuesday in regard to the recent terrible snow storm experienced in that city:—"During Monday night also the electric light went out, and several persons were found frozen in the snowdrifts, while since the storm scores of injured persons have been taken to the hospitals. Seventy-five trains were stuck on the railway lines within a radius of fifty miles of the city. On the Western Union system half-a-dozen wires are working to the West, and communication is by this means maintained with the South, and with places up the coast. Direct communication with Philadelphia and Boston is still interrupted. Intelligence has reached here from the latter place, via London, stating that a terrific storm prevailed for two days, blocking the railroads and prostrating business. The storm is described as the severest known there for fifty years. There is some improvement in the railroad traffic here, but great interruption still

continues. On Wednesday the *Financial News* correspondent cables:—"Private wires and telephones are alike useless, and the effect on New Yorkers, who are as much accustomed to the use of the telephone as they are to their daily bread, can hardly be imagined. We are completely snowbound, and shut off from the world, except by the Commercial Cable, which, unfortunately, cannot convey food or stores. Consequently the prices of coal and food are doubled to-day. The losses of the Western Union Telegraph Company, in repairs and loss of revenue, will be very heavy. The storm is abating, but the cold is intense, and traffic is still suspended."

Telephony at Macclesfield. The Lancashire and Cheshire Telephone Company have now completed their operations so far as the local connection of the telephone is concerned, and during the past week the ten subscribing Macclesfield firms have been in daily communication. It will be some weeks yet before the trunk wire can be laid to Manchester and throughout the immediate district; when this is accomplished, subscribers will be able to communicate with the principal commercial houses in the two counties from which the Company derives its name, a boon which cannot be over-estimated. The central office of the company is at the *Commer* office. Should the undertaking receive sufficient encouragement from subscribers and we have no doubt it will when the benefits are sufficiently well known it is the intention of the company to establish a call office at the centre in Macclesfield, where, on the payment of a certain fee, the general public can communicate with any of the company's subscribers. The company have run free wires to the Macclesfield Infirmary and the Volunteer Fire Brigade. Up to the present time, connections have been established between 60 towns in Lancashire, Cheshire, and North Wales; while several towns in Yorkshire may be communicated with by arrangement with the National Telephone Company. The total number of subscribers approaches 5,000, and new names are being continually added to the list. Under the system pursued by this company, not only are any two members enabled to converse together, but it is also arranged that outsiders shall be able to communicate with each other by means of public call offices at various parts of each district. The co-operation of the Post Office has been secured in Manchester, Liverpool, and Blackburn, in order that telegrams may be sent to, and received from, the telegraph office, through the telephone, without loss of time necessarily occupied by the messenger.

The Electric Light in Paris.—A large number of petitions, praying for a prompt solution of pending questions in relation to electric lighting, have been laid before the Municipal Council. The trading classes in the quarters of St. Germain-de-l'Auxerrois, the rue St. Honore, the place Vendôme, and the faubourg Montmartre demand the establishment of central stations; whilst the inhabitants of the quartier des Halles demand that the *Société d'Eclairage Electrique* in this quarter may be provisionally authorised to establish overhead cables. The most active interest, in fact, prevails in regard to the extension of electric lighting, and M. Lyon-Alemand, the reporter to the third committee, has, under these conditions, undertaken to send in his report immediately, with a view to expedite matters.—The fire which recently occurred in the underground portion of the Halles has had the effect of drawing the attention of the municipal council to the

danger of using gas in such localities. It has been urged by M. Lamouroux that not only from the point of view of the prevention of fires, but from those also of facilitating the work and preserving the health of the labourers employed in this market, a complete solution of the difficulty is to be found in the substitution of the electric light for gas. At the present moment a most favourable opportunity for so doing is to be found in the fact that it is proposed to construct works for the generation of the light in the underground portions of the meat pavilion. Unfortunately, the Administration and the committee of the Municipal Council are not in agreement as to the object and purpose of the works in question. The committee regard the lighting of the hall as altogether a secondary matter, and considers that the works should be devoted to the general distribution of the light in Paris. The administration, on the contrary, considers that the proper way of commencing business would be to provide adequate illumination for the market itself. It is to be hoped that this difference of opinion will not have the effect of retarding the construction of the works, which are urgently required. In the meantime the electric light has been actually introduced in certain portions of the underground premises which are being restored, and where the installation of gas would, in the opinion of the Administration, be disadvantageous. An electrical installation has therefore been provisionally carried into effect: for which, on the motion of the Prefect of the Seine, the Council has voted a credit of 25,000fr.

Liverpool Electric Co.—The annual meeting of the Liverpool Electric Supply Co. (Limited) was held on Monday, Mr. Arthur Hill Holme in the chair. The report and accounts were passed, and a dividend of 7 per cent. for the past year was declared, and an addition made to the reserve fund. The retiring directors, Mr. S. H. Holme and Mr. D. de Ybarrondo, and Mr. W. L. Jackson, auditor, were re-elected. Commenting upon this meeting, the *Courier* says:—“In 1883 the Liverpool Electrical Supply Company was formed, apparently as a sort of tentative effort to give the electric light a permanent local home. The experiment has succeeded. The original capital was £10,000, but the business expanded and the capital was increased to double that amount, and it will be seen that at the meeting yesterday the directors agreed upon a dividend of 7 per cent. This circumstance suggests that there is not only a demand for the electric light, but that this demand can be met with substantial profit to the shareholders. Under these circumstances it is not surprising to note that the company have decided to make their business more commensurate with the requirements of the city. To this end they are increasing their capital to £200,000, including the shares to the value of £20,000 already subscribed, and they intend to supply the electric light to all who seek it within a very wide area, comprising the more important residential parts of Liverpool as well as the great business centres. It is arranged also that the supply shall be by day and night at a regular fixed charge, measured by meter. There has been a supply station in Rose street for four years, and a second station has recently been started in Tithelam street; while a third and more important one is approaching completion in Harrington street. Besides the use of electricity as an illuminant, it is naturally expected that its utility as a motor will become more generally recognised when it is brought within reach of those who need ‘power’ for trade or other purposes. There is one circumstance that must secure for the company’s

prospects a careful consideration on the part of the public: the ten fold enlargement of the undertaking is promoted by responsible Liverpool gentlemen, who are fortified by the experience already gained. With a capital of £10,000 the dividends were 5 per cent., while with a doubled capital the dividends have reached 7 per cent. a fact which seems to indicate that proportionately larger profits may be expected from the further extension of the business. The enterprise is of importance to the whole community, and not merely to the investing portion of it, and its development will be watched with considerable interest.

Royal Colonial Institute. A meeting of the Royal Colonial Institute was held on Tuesday evening at the Whitehall Rooms of the Hotel Metropole, when Mr. J. Henniker Heaton, M.P., read a paper on “The Postal and Telegraphic Communication of the Empire,” of which we can for the moment give only the following brief abstract. The chair was taken by Viscount Bury, and there was a large attendance. In the course of his paper Mr. Henniker Heaton expressed the opinion that the Imperial and Colonial Governments should unite to acquire all the existing Imperial telegraphs, and to construct what other lines might be deemed necessary. He thought that telegrams could be profitably sent between England and Australia for 1s. a word. The Pacific cable could easily be made to transmit 10 million words a year. That alone would give a revenue of £500,000 a year, sufficient to bear its share of the interest on capital, to pay the working expenses, and to leave a margin of profit. Looking back upon the past, they saw every reason for encouragement. It was only 50 years ago that a few scientific men made the experiment of electric transmission between Euston and Camden Town, in the north of London—a distance of about a mile. The jubilee of the telegraph had just been celebrated in the capital of the Empire. Australia was not connected with the telegraphic system of the outside world till 1871. To-day messages were transmitted between London and Dublin at the rate of 462 words per minute. The number of telegrams sent through the post offices of the United Kingdom averaged nearly a million a week; and between any two points within the United Kingdom a telegram could be sent for sixpence. There were now 115,000 miles of submarine cables—as much as would go round the world five times; and a message could be sent all round the world in twenty minutes. Those cables carried a hundred million words every year. He saw that the accidental reduction in the rate between England and America had led to an increase of 150 per cent in the traffic. “Hands across the sea” would indeed be no figure of speech when almost the poorest would be able to communicate, momentarily, with his friends at home, and they with him. Whether for the purpose of maintaining old friendships, old relationships, the ties of home and kindred—whether for developing the exchange of produce and of manufactures, so that each separate part of the Queen’s dominions should partake of the other’s wealth, to the increased prosperity and happiness of them all—whether for defending this great but scattered Empire against those who might disturb her peace and check her career of tranquil progress—there had never yet been devised so sure an agency as the throbs of the electric pulse, signalling with unfaltering regularity, night and day, the thoughts and wishes they would impart to their fellow-subjects in every clime, bringing them near in spirit though not in body, and effecting that unity of interest and sympathy in which were mainly laid the foundations of the British Empire.

ELEMENTARY TESTING SUITABLE FOR ELECTRIC LIGHTING SYSTEMS.

BY THOMAS GRAY, B.Sc., F.R.S.E.

(Continued from page 200.)

Resistance Slides.—In the use of the different forms of resistance boxes, which have been described above, the Wheatstone's bridge is generally made up of the resistance to be measured; two constant resistances, and one variable resistance, together with the battery and the galvanometer circuits. It is quite clear that instead of using two constant and one variable resistance we might use one fixed resistance, and vary the ratio of the other two until balance is obtained. When proper arrangements can be made for the purpose this method is convenient and accurate, and allows the balance to be very quickly obtained. The arrangement is illustrated diagrammatically in Fig. 10, in which R is supposed to be a set of resistances of any convenient form, to be used as the invariable side of the bridge during any one test; but capable of variation, so as to be suitable for the measurement of different resistances. One end of the resistance R is connected to the end A of a set of equal resistances A B (a Thomson's resistance slide) and the resistance x , the magnitude of which is to be measured, is connected between the other end of R and B. The battery E and the galvanometer G may be supposed connected up as indicated in the diagram. When a single slide is used it usually consists either of ten or of one hundred equal resistances

FIG. 10.

and a slider such as that shown at s is arranged on a slide rod r fixed in front of the blocks, which connect the resistances in such a way that when the slider is moved backwards and forwards it puts the galvanometer in contact with the different blocks in succession. When measuring a resistance in this way the resistance R is made nearly equal to the estimated value of x , the battery and galvanometer circuits closed and the slider moved until the galvanometer deflection is nearly zero. If the slider is near one end of the resistance slide it should now be readjusted so as to be more nearly equal to x , and the position of s , which gives no current through the galvanometer, found. If no such position can be found then the two adjacent positions which give opposite currents through the galvanometer should be found, and the galvanometer deflections noted. Let a and $a + 1$ be the numbers of the blocks in these two cases, and let d and d_1 be the galvanometer deflections. Then the position of the slider which would have given zero deflection is on the resistance between a and $a + 1$ at a distance $d/(d + d_1)$ of its length from the end connected to the block a . Hence the proper reading for the position of the slider would be $a + d/(d + d_1)$, and assuming n resistances in the slide, the value of x would be obtained from the equation

$$\frac{R}{x} = \frac{a + d/(d + d_1)}{n - \{a + d/(d + d_1)\}}$$

or
$$x = R \frac{n - \{a + d/(d + d_1)\}}{a + d/(d + d_1)}$$

In the arrangement illustrated in Fig. 10 a double slide is supposed to be used. In this case the slide A B consists of

eleven or of one hundred and one resistances, while the second slide C D consists of ten or one hundred resistances the aggregate magnitude of which is double that of each of the resistances in the slide A B. The ends of the slide C D are connected to a double contact slider S, the two contact springs c_1, c_2 of which are insulated from each other. The contacts of the slider S are made to embrace two of the resistances in the slide, so that the total resistance between the ends of A B is always either ten or one hundred times the resistance between a pair of adjacent blocks.

The second slider thus forms a vernier by means of which the position of the slider S, which gives an exact balance of resistance, can be more nearly obtained. Suppose an exact balance has been obtained with the sliders S and s , in the positions shown in the diagram. Then the value of the resistance x is

$$x = R \frac{100 - 56}{56} = R \frac{44}{56}$$

When exact balance cannot be obtained, the proper position, intermediate between two contact blocks, for the slider s is to be calculated from the deflections of the galvanometer, in the same manner as has already been indicated for the case of a single slide. This vernier principle might be still further extended, and triple or quadruple slides used, in which case, if the last slide contained n resistances, each equal to w , the next would contain $n + 1$ resistances, each

equal to $\frac{w}{2}$; and the next $n + 1$ resistances each equal to $\frac{w}{2} \times \frac{n}{2} = \frac{n^2}{4} w$, and so on.

It should be observed, however, that when only one slide is used the resistance of the contact between the slider and the block or the slide rod r is in the galvanometer circuit and does not affect the accuracy of the result, but when a vernier is used the contacts of the slider S form part of the resistance of the vernier slide, and hence may introduce error in the result. It is not advisable therefore to push this vernier method so far as to make the resistance of the last slide less than 10 ohms or so. The form which is most convenient and most commonly adopted for these slide resistances has a circular row of contact studs and a contact arm which revolves round an axis at the centre of the circle. The main slide has in this case a double contact arm to which the vernier slide is connected. These circular slides generally contain one hundred or, if it is a main slide, one hundred and one separate resistances, each of which is either 100 or 1,000 ohms in the main slide and 2 ohms or 20 ohms in vernier slide. In the use of such slides for the measurement of resistances it is important to bear in mind that the greatest sensibility of the slide arrangement is obtained when the main slider is so placed that equal ratios can be obtained, that is, when S bridges from 4 to 6 and the vernier s is at 10, or when S bridges from 5 to 7 and s is at zero. Passing from this position we get the following ratios in succession:—

1 to 1.0000
1 to 1.0408
1 to 1.0833
...
1 to 32.333
1 to 49.000
1 to 99.000
1 to infinity.

From this table it is quite clear that a slide resistance can not be used with advantage when the ratio of the fixed resistance to that to be measured differs much from unity. It may be remarked that several short slides joined up so that each acts as a vernier on the one before it, is for the same range more economical of contact studs and resistance bobbins than two long slides. Thus, three slides, each with eleven resistances, and one of ten resistances, give, when properly joined up, the same range as two slides of 101 and 100 resistances; while in the first there are only 43 contact studs, and in the second 201. For multiple slides in this form straight slides have an advantage in compactness over circular ones. Thus, an arrangement containing five slides of eleven resistances, and one slide of ten resistances, can

be arranged on a moderate-sized rectangular box, and gives great sensibility through a considerable range of the main slide. Each of the main resistances may have 1,000 or 10,000, or 100,000 ohms resistance according to the purpose for which it is intended. With an arrangement of six slides, the main slide resistances require to be at least 1,000 ohms, so as to avoid error due to resistance of contacts in the last slide. When the slides are arranged for equal ratios in the bridge, each step of the last vernier makes a change of only two five hundred thousandths in the ratio, while with the slides arranged for a ratio of 9 to 1 each step of the last vernier makes a change of ten five hundred thousandths in the ratio. Hence such a slide gives ample sensibility through a range of from one to ten on the main slide or for the measurement of resistances varying from a tenth to ten times the fixed resistance. Slide resistances of the form just described are convenient for the measurement or the comparison of high resistances and, as we shall find later, for the measurement of capacities, but when the resistances to be measured or compared are small it is much cheaper and better to adopt some arrangement which has a small total resistance and which at the same time admits of a continuous variation. Such an arrangement is Kirchhoff's wire bridge illustrated in Fig. 11. It consists of a wire A B stretched in front of a scale of equal divisions and securely soldered at each end to thick copper straps which are screwed to a base of dry wood. The copper straps are usually made of the form shown in the figure, passing along behind the scale, leaving four gaps which may be closed either by resistances as indicated in the figure, or by strips of copper made with notches to fit under the binding screws, which are represented by the double concentric circles in the figure. The wire forms the slide and is, in this form, usually one metre in length between the solderings. The wire may be of almost

FIG. 11.

any material, but should not be readily corroded by exposure to the air and should be hard enough not to wear rapidly by the action of the contact key upon it. Platinum silver and platinum iridium alloys are much used, but platinoïd is much cheaper and suits well. A slider S, standing on three feet, is arranged to slide along in front of the scale, which is raised an inch or more above the surface of the base plate, so as to be on a level with the top surface of the slider. Either a single index line or a vernier is engraved on the top of the slider so as to facilitate accurate reading of the position of the slider. The slider is furnished with a binding screw attached to the top of a vertical metal rod, the bottom end of which is sharpened and can be brought into contact with the wire by pressing on the top of the binding screw. This bridge is usually connected up as shown in the diagram, where E is the battery and G the galvanometer. The battery circuit is shown interrupted by a single lever key, but in this as in all other arrangements of the kind, it is preferable to use a reversing key. The length of the slide is increased at will by the introduction of resistances a and b in the two end gaps. For most purposes for which this bridge is used a and b are equal, but they may have any ratio which may be required, depending of course on the ratio of the resistances to be compared. The resistances to be compared are shown at c and d . Suppose in the first place that c is nearly equal to d . Then a and b are made so nearly equal that the middle of the total resistance a, b , and the slide wire and its connections, is near the middle of the wire. The position of the slider S is found, which gives no deflection, when the circuits of E and G are both closed. The resistances c and d are then interchanged, and the position of S again found, which gives an exact balance. These positions should be equal distances on opposite sides of the

middle of $a + b + A B$, and if the value of one division of the wire in terms of the whole resistance in its circuit is known, the ratio of c to d can be at once calculated. The case here considered is the one of most common occurrence, because such a bridge is generally used for the comparison of standards or other resistances of equal value. In order that the method may be convenient, it is necessary either to have a perfectly uniform wire, or to know the relative value of its different parts, and also the percentage value of unit displacement along the wire. Methods of finding the relative value of the different parts, or calibrating such wires, will be given below. The percentage value of unit displacement, with any particular resistances a and b in the circuit, is best found as follows. Substitute for c and d two known resistances taken, let us suppose, from a box of resistances. Find the position of S which gives a balance; and then, increase one of the resistances in the box by the addition of a small known resistance, and again find the balance. The percentage value of the displacement of S is then the same as the percentage change made in the ratio of the resistances. Take, for example, an ordinary resistance box; and, c and d being removed, join in, by means of the terminals e and f , the resistances $a + b + A B$, and the connecting pieces, as if their total resistance was to be measured. Join the galvanometer circuit from the slider S to the junction between what is usually taken as the variable resistance in the box and the divided resistance. Now employ one of the hundred ohms of the divided resistance and one hundred ohms in the box and find the position of S which gives a balance, then increase the resistance in the box by one tenth of an ohm and again find the position of S which gives a balance. Let the number of divisions S has been moved between the two experiments be n . Then a displacement of S by n divisions from the middle position indicates, in the ordinary use of the bridge, a difference of one tenth per cent. between the two resistances c and d . The values of two tenths, three tenths, and so on may be found experimentally in the same way,

FIG. 12.

or if the wire be calibrated they may be calculated. It must be remembered that the displacement for two tenths is not quite double that for one tenth, because the sensibility becomes less and less as we approach the end of the slide. It must also be remembered that when double readings are taken by interchanging c and d , half the displacement of S is the displacement from the centre. When the wire is calibrated the experiment just described gives the means of calculating the effective total length of the wire in scale divisions, and hence it is better in this case to calculate the ratio of c to d from the readings on the scale. Suppose with c and d placed as in the figure the slide is found when balance is obtained to be n divisions from g , and when c and d are interchanged it is m divisions from g . Then $c/d = n/m$, when the resistances c and d are not nearly equal, and their value either actual or relative is wanted accurately, it is better to compare them separately with known resistances to which they are nearly equal. If their relative value is only wanted approximately the additional resistances a and b may be dispensed with, and the ratio found directly by means of the wire itself. For use in this way the connecting pieces between the battery and the ends A and B of the wire should be included in the calibration, so that no estimation of their value is required. When the resistances to be compared are low and great accuracy is desired, as for instance, in the comparison of standard ohms, it is advisable to introduce the resistances by mercury cups instead of binding screws. The mercury cups should either be wholly of copper or have copper bottoms, and the ends of the resistances should rest against the copper, the mercury being used only to insure contact. A convenient and inexpensive form of wire bridge is shown in Fig. 12. It has the great advantage that it can be made up by the user with little trouble and is capable of giving

very accurate results. A wire, w , which may be copper, but preferably of German silver or platinum, is stretched on a board, or a table, round an insulating block B and held by a clamp of vulcanite A placed at a short distance from the ends. The wire should not touch the board or table, but be suspended above it by means of A and B, or, if it be made long, by means of several clamps like A. A nest of mercury cups, C_1, C_2 , are placed in a block of paraffined wood or vulcanite fixed to one end of the board, in such a way that the level of the tops of the mercury cups is about the same as that of the wire. The end of the wire is soldered to a thick rod of copper, bent in the shape shown in Fig. 13, and well amalgamated with mercury. The reason for bending the rod in this way is to prevent the mercury touching the soldered junction.

FIG. 13.

The mercury cups may very conveniently be made of copper, of the shape and size shown in Fig. 13, and fitted into holes in the wood or vulcanite. They can then be lifted out and emptied, or they can be used for another instrument if required for such a purpose. A number of cups of this form are exceedingly convenient, either for a laboratory or for a testing room. Should greater sensibility be required than is obtained by the bridge wire alone, auxiliary resistance may be introduced between c_1 and c_2 , and between c_3 and c_4 , while c_2, c_3 and c_4, c_5 are joined by the resistances to be compared. Since w can be made several metres long in this case, the auxiliary resistances are not often required; and in this case c_2 and c_3 are removed and c_1 placed in the hole h , the resistances to be compared being placed between c and c_1 and between c_1 and c_5 . When used in this way the resistances may be interchanged by lifting the two ends of the bridge wire out of the cups and crossing them, thus interchanging the sides of the wire. The wire may be divided into parts of equal resistance by calibration marks made on the board at the different divisions, and a movable scale used to subdivide the sections between the calibration marks.

INDEPENDENT ENGINES IN INDEPENDENT STATIONS.*

BY WILLIAM LEE CHURCH.

The service of electric lighting differs from other forms of manufacture in requiring more horse-power per square foot of floor space; in requiring higher speeds; in demanding the power in larger units, in compelling a closer and more uniform regulation; and in requiring more rapid and constant extensions. It will be observed that these peculiarities require individual and special treatment in the generation and distribution of power, and engineering practice as determined in other means of manufacture may be sadly at fault when applied to electric lighting.

It has become an axiom among experienced station managers that the money is made or lost between the shovel and the belt; in other words, other things being equal, the dividend earning capacity of a station is determined by its steam plant, to which the electric apparatus is in the nature of an accessory.

Incandescent lighting has not until recently made a brilliant record as an investment, and much of the disappointment is directly traceable to the culpable ignorance of the principles of steam engineering which has been displayed. A man who will not venture to cut himself a 2,000-dollar vest will not hesitate to exercise his amateur talent upon a steam plant, upon the economical and reliable

performance of which depends an investment of 100,000 dollars, and the public service of a city. A long and critical experience in this branch of industry has grounded us in the conviction that no incandescent station can hope to be financially successful, under the ordinary conditions of competition, unless based on independent dynamos belted direct from independent engines. Throughout this paper, therefore, we desire to keep constantly in view the opposite systems, namely, a station containing a given number of dynamos of two or three different capacities, each belted direct from high-speed engines of corresponding rating, and, on the other hand, the same station with the dynamos driven from one or two slow-speed engines transmitting their power through one hundred feet of shafting, more or less, encumbered with clutch pulleys. Having these pictures well in mind, we inquire:

What are the essential requirements of a first-class steam plant in an incandescent electric light station? Taking them up in the order of their importance we unhesitatingly say first, and always foremost, *absolute reliability for continuous running.*

The electric light company contracts to supply the demand of a diverse and exacting public, and that public expects to find its light on tap at every moment of every hour of every day in the year. Failure of service in ever so small a degree is palliated by no excuse. Complete reliability is the condition of popularity, confidence, and patronage, without which all the other economies and excellencies go for nothing.

Again, electric lighting, perhaps more than any other industry, has its earnings directly affected by the shutting down of its power, since it sustains a direct financial loss for lights out, aside from custom and reputation, not easily regained. Subdivided power reduces this risk to a minimum, and, properly directed and applied, obviates it altogether. In a station using, say, 2,000 horse-power, say in the shape of two large engines, loss in lamps in one night by the shutting down of one of these engines is equal to one half the cost of an independent engine on the subdivided plan, in other words, as tersely expressed by a manager of experience, a company might better, for peace of mind, reputation, and cash balance on the books, throw a 60 horse-power engine into the scrap pile than to shut down the station one hour. The service of electric lighting is similar to the editing of a daily paper, in that lost time can never be regained. Most industries can make up lost time by working overtime, and pushing their business in various ways, but in electric lighting

"The mill will never grind with the water that has passed."

Passing from argument to instance, we cite the recent experience of one of the largest stations in the country, operating in the neighbourhood of 20,000 lights. The station, as originally planned, was driven from a pair of Corliss engines, each having a cylinder 28 in. in diameter by 48 in. stroke, and belting to a countershaft 4½ in. in diameter by about 50 ft. in length. From this countershaft are driven five dynamos, having an aggregate capacity of six thousand 16 candle-power lamps. Clutch pulleys 8 ft. in diameter, which are the means of disconnecting the dynamos when not in use with similar clutch pulleys for exciters. The remaining dynamos in the station are each of 2,500 lights capacity, and each driven by a 200 horse-power independent engine belted direct. Recently, in the middle of the heavy run of the evening, one of the clutch pulleys broke in some of its parts, necessitating the immediate shutting down of the 6,000 lights besides doing considerable damage and involving danger to the employees. The extinguishing of such a large number of lights at the important hour of the run was a blow at electric lighting of the severest nature, and working serious inconvenience to public gatherings. It happened that one of the independent engines, with its dynamo, was immediately available, and was started within two or three minutes so as to take up a portion of the load of the large engine. Intense heat, at a subsequent time, a key became loose on the valve gear of the engine, necessitating another stop several minutes. On still a third occasion the crank became uncomfortably hot, and was carried through the run only at a great risk and labour. This illustration is used one among many of the almost evident fact that no elec-

* Paper read before the National Electric Light Association.

on can afford to hang its whole business upon any of motive power, particularly when that motive is distributed through the complex mechanism of shaftings, clutch pulleys, &c., involving a lot of bearings, broken pulleys, defective frictions, &c., not any one of which may shut down a station. Had these dynamos been each an independent engine, the accidents above mentioned could not have occurred in the nature of the thing. I do not assume to say but that accidents of some kind do occur in any piece of mechanism; but the division of motive and generating capacity into comparatively small independent units, affords a practical distributing the danger, so that it is essentially reduced, that is to say, had a stoppage of any one engine in a similar instance occurred from any other engines, with their dynamos, would easily distributed the load for a short time, without any loss or danger whatever, and the service would have been interrupted while the repairs were being made or they remedied.

It has been incidentally remarked by a gentleman with the practical operation of a station, that independent engines afford a safeguard against danger from short circuits, inasmuch as currents of the short circuit will not stop an independent engine and slow it down, thus removing the danger. If the dynamo is driven by a large engine, motive power will not respond to a short circuit until the short circuit becomes equal to the capacity of all the connected dynamos plus the power in the engine. Practically, therefore, an engine of this type will not feel the short circuit, but will keep running until something burns away.

One of the great advantages of the steam plant which is most obvious, and which appeals most strongly to the electric light company is the economy of fuel.

For the purpose of large slow speed engines rely upon the superior fuel of this type as the sole effect to its advantages. All managers unhesitatingly admit the superiority of transmitting the power directly and not from the engines to the dynamos, and more or less concede that in its performance the high-speed engine is also equal to the running qualities and durability of a slow speed engine. If with this, say they, we could obtain the same efficiency of the Corliss engine, no man would hesitate to decide in the favour of the convenient, and independent small engine. We take the matter at once by the beard, and desire to state that, in the case of incandescent stations operating under ordinary conditions, and otherwise equal, except only in their mode of transmission, that one which has independent engines will show on its monthly report sheet, a small amount, but from one third to one half less coal consumed per hour than a station driven from a single engine with countershafting, both types of engines being non-condensing. We go yet further, and state that independent engines, under many conditions, will about equal the monthly coal account an equivalent slow-speed engine. This is a fact so incontrovertible, when candidly investigated, that we do not propose to demonstrate it, but merely to illustrate it.

I submit the prompt inquiry, "Will not a high-speed engine use more coal per horse-power per hour than a low-speed engine?" Yes. "How much more?" Size for size, load for load, not over 10 to 12 per cent. Score against the high speed engine, and again ask, "Will not several small engines use more steam than one large engine, even of the same type?" Yes. "How much more?" Load for load, possibly another 10 per cent. Score 20 per cent. against the high speed engine, and ask how an admitted loss of one pound of coal in a month can be reconciled with the statement of a monthly saving of 30 to 50 per cent. in favour of independent engines. Answer, simply because we have to deal with the facts as they exist in fact, and not as we assume them to be.

Now why independent engines can overcome their lack of initial economy, and pass a large percentage of initial economy to their credit, are mainly two. First, the use of a countershaft implies power to run it.

Indicator diagrams show that the real load of such a plant varies from 12 to 20 per cent. of the gross horse-power under full load when in ordinary good condition, and not infrequently rises to 30 per cent. and over, with badly lined shaftings and badly drawing pulleys. Moreover, it must be borne in mind that the dead loss is nearly a constant quantity, and if it amounts to 20 per cent. of the full load it will under partial load equal, and even exceed, the net power transmitted to the dynamos. It may easily happen, and doubtless does happen every night in every station thus far, that from midnight to morning two or three horse-powers are expended in the cylinder for each effective horse power recovered at the dynamo pulley.

Thus, by one stroke and by a single item, is the concealed advantage of the larger engine reckoned in coal per horse-power, practically swept away, and large and small engines left standing on an equal footing, prepared to submit to the still more searching question, "What is the cost from hour to hour of the power actually expended in meeting the fluctuation of the load?"

To consider for a moment some abstract fact in steam engineering, we must note that the steam engine develops its maximum economy (i.e., minimum consumption) only over a limited range of its power. Under normal conditions of pressure, say eighty to a hundred pounds in the boiler, this minimum consumption is found only between the points of $\frac{1}{2}$ and $\frac{3}{4}$ cut-off. At its rated power, therefore, the single large engine of the Corliss type will consume as little as 26 to 28 pounds of water (steam) actually fed to the boilers per indicated horse power per hour; and if the economy were not affected by the load, we could represent the rate of consumption by a straight line. If overloaded, however, the rate of water consumption rises, in which horizontal distances on a diagram represent the actual points of water consumption, the curve, therefore, being a curve of efficiency at varying loads, it will now be particularly noted that, when the load rises for an overload, it also rises for an underload, and very much more rapidly. This is well understood to be partly from excessive condensation due to over expansion, and partly from the greater ranges of leakage under short cut-offs. Considering the actual performance of a 400 horse power engine at varying points of cut-off, the engine can be at its best only over a limited range—say, from 325 to 400 horse-power. An overload is, of course, mechanically injurious which limits the possibilities in that direction. As the load falls off below $\frac{1}{2}$ cut-off, the steam rate increases at an enormous ratio: so that at 200 horse-power the engine is using 50 per cent. more than its normal rate, i.e., at 200 horse-power it is actually using the gross amount of steam which would give 300 horse-power if used in a 300 horse-power engine. At 100 horse power, waste is fully 100 per cent.; and the steam used should develop, not 100 horse-power, but 200 horse power, if used in a 200 horse-power engine.

It now remains to determine if the conditions actually obtained in electric lighting stations are such as will enable a single large engine to develop its normal economy; and, if not, then they are such as will enable the smaller independent engine, with a lesser initial economy, to reach a better gross result, under the inevitable conditions as they are found to exist.

(To be continued.)

EARLY TELEGRAPHY.

Some interesting information has recently been given by Mr. T. Home, relative to the first telegraph on the Great Western Railway from Paddington to Slough. We shall allow Mr. Home to give his experience in his own words:

In 1842 the Directors of the G.W.R. very kindly and very generously—regarded by Mr. Cooke as such, I well know—gave Messrs. Cooke and Wheatstone permission to lay down their telegraphic wires from Paddington to Slough for experimental purposes. In the first instance Mr. Cooke used four copper wires, thickly covered with cotton, like that used for ladies' bonnets, and untiedly drawn through a resinous solution, and finally secured in lin. iron pipes which he slightly buried below the surface on the near side of the down rails from Paddington to Slough. The insulation, however, by this plan of conducting the wires proved imperfect, which no doubt was caused by

the displacement of the resinous coating, and probably that also of the cotton, by the friction in drawing the wires through the pipes. This difficulty for a time appeared a formidable one to Mr. Cooke, and gave him great anxiety, interesting as it did with correct signalling, but he very shortly overcame it by procuring a quantity of foreign peels, 15ft. or 16ft. long, to which he suspended the wires as now done, and used brown earthenware insulators at the points of suspension to the posts as now. The insulation was then found to be all that could be wished, and signals were then sent with great rapidity and unerring fidelity.

Up to March, 1843, suitable offices had not been provided for the use of signalling, but immediately after that date the directors of the G.W.R. very generously provided suitable office accommodation for the patentees, both at Paddington and Slough stations, and I consider the public is greatly indebted to the thoughtful generosity and kindness of the said directors for the early introduction of electric telegrams, owing to the facilities rendered by the directors to Messrs. Cooke and Wheatstone in carrying out their experiment on a more extended scale than they had been able to do.

I am much indebted to Mr. Higgins, of the G.W.R. Company, Paddington, for the following information, which he has kindly procured for me at a vast amount of trouble in searching the Company's records:—

"G.W.R., London Terminus, Paddington,
" March 8th, '87.

EXTRACT.

"Reference has been made in our records, and the first mention of the subject was in March, 1843, when, on the application of Mr F. Cooke, authority was given by the directors for the creation of offices at Paddington and Slough stations for the purposes of the Electric Magnetic Telegraphs. " J. D. HIGGINS.

"To Mr. Thos. Home, The Kilns, Brill, Bucks."

Some of your readers may probably recollect that the telegraph offices referred to were located as follows. That at Paddington Station was the first room on the right at the top of the stairs leading to all the principal offices of the Company at the arrival platform and that at Slough stood on the summit of the mound, plated with shingles, near the railway bridge on the right on leaving the station for Windsor.

Suitable offices having been secured, the patentees were in a position to send any telegrams required either for the G.W.R. Company or the general public. As the G.W.R. Company did not care to purchase this line of telegraph, as Mr. Cooke had hoped they would, and as Mr. Cooke was naturally very anxious to get some return for the very heavy cost that he had incurred up to this period, I suggested to him that he should let the telegraph in question to me at a low rent, and I would open the offices at Paddington and Slough to the public as an exhibition at a small entrance fee, and would send any telegrams required at a small charge. This suggestion met with Mr. Cooke's entire approval, and I forthwith entered into possession as "Licensee" at a rental of £170 a year, with the understanding that all telegrams the G.W.R. Company required to send were to be free, as some slight return for the kindness of the directors in giving the patentees the free use of their line for experimental uses. This privilege of free telegrams was only used on special occasions. I continued "licensee" until the patentees sold their several patent rights to the Telegraph Company, floated in 1846 to extend its ramifications.

Having entered on my unique undertaking as "licensee" of the grandest, most wonderful, and certainly the most valuable and interesting discovery of the age, I lost no time in making known to the public, through the best recognised channels, the fact that the telegraph offices at Paddington and Slough were open to them on payment of 1s. and that telegrams could be sent for 1s. each, messenger extra. With the kind permission of the G.W.R. directors I had large posters displayed on the walls of all their stations, the one displayed by many tradesmen outside their shops in various parts of London, engaged the services of a small regiment of those apparently indispensable "sandwich" gentlemen well equipped with handbills for judicious (!) distribution in their perambulations of the great highways centring to the City; and finally by causing advertisements to appear in the leading London daily and weekly papers, the editors of which rendered me good service by every now and then kindly notifying to the public that 1s. spent in paying a visit to Paddington and Slough offices could not fail to ensure the most gratifying results. I name this to show your readers the steps taken by me, and at my sole cost, to bring the merits and capabilities of the telegraph well home to them, and in doing as described, I no doubt rendered the patentees good service by at least aiding to hasten its general adoption, which shortly after resulted; your readers, however, must feel surprised when informed that my undertaking signally failed in the realisation of that big pile I had fondly hoped would be an accomplished fact in the near future. Young and inexperienced I had unfortunately formed to high an estimate of public taste, as evidenced by the extensive patronage accorded other exhibitions of incomparably less merit. Nevertheless, pleasure even at this distant period is derived by a retrospect of the many incidents of my telegraphic days, and from the fact that I have had the honour—if empty—of explaining the working arrangements of the various telegraphic instruments then patented by Messrs. Cooke and Wheatstone to the most eminent men of the day, including the bulk of the aristocracy and several of the crowned heads of the principal European countries when on a visit to this country during the years 1843 to 1846.

The honour of having sent the first paid telegram in this country is due to myself beyond doubt, and I it has occurred to me as a singular coincidence that the charge made for the first telegram should be the same as that fixed by the Postmaster General. However, there is this marked distinction, I never limited the sender to number of words. No reasonable person, however, will find fault with the present charge for inland telegrams.

The first electric telegram sent in this country specially on behalf of Her Majesty Queen Victoria was received by me at Paddington Station, from my Slough correspondent soon after 4 a.m. on the 6th August, 1844, which was to request me to forward letters I had long previously received from Windsor Castle to several respectable addresses, and which were to summon the Cabinet Ministers to Windsor Castle so that they might have the honour of being introduced to H.R.H. the Duke of Edinburgh, whose advent had been foretold just 23 days earlier, and during which 23 days and nights I had been made an involuntary prisoner in the Paddington telegraph office, anxiously awaiting instructions as to the said letters, which in due time I despatched by special messengers in cabs, and to the credit and loyalty of the said Ministers it should here be stated that they began to arrive at Paddington station within an hour and a half of my receiving the telegram. Those first to arrive paid me a visit to see the telegraph while waiting the arrival of others, and expressed, as all did, the greatest pleasure in seeing it worked. One noble lord, on learning the length of time I had been made "prisoner during Her Majesty's pleasure," told me he should certainly bring the fact to Her Majesty's notice.

Three special trains were requisitioned that morning to convey the Ministers to Slough en route to Windsor Castle. The last of the three trains had one minister only, and, unless my memory fails me, that was no other than the Iron Duke, whose train accomplished the journey, 18½ miles, in 18½ minutes. The driver of the Flying Dutchman and others will take note of this, and may rely on it as a fact.

During the last four or five days and nights of anxious waiting I was honoured with the company of the representatives of each of the following papers:—*Times*, *Herald*, and *Past* who, on being put in possession of the particulars of the birth of His Royal Highness, took their departure to their respective offices, and the long looked for news appeared on the breakfast table of Londoners in the shape of a second edition. I name this to show the heavy sacrifices made by newspaper proprietors to secure the first intelligence of interest for their respective customers. I made no charge for the information, but was substantially rewarded by each.

As early as 1843 the telegraph was made use of by the police on Ascot race days, by the detectives at Paddington Station making known to their brother officers at Slough Station the movements of well-known bad characters of thievish propensities, who, on receiving a friendly warning on arrival at Slough Station, thought themselves put in an appearance at the racecourse, and either loitered about Slough or took an early return train.

The next telegram in importance to that relative to the birth of H.R.H. the Duke of Edinburgh was that which was sent up at Paddington respecting the Salt Hill tragedy, and which enabled me to have the Great Western Railway Company's sergeant of police (Williams) in readiness on the arrival at Paddington of the 8.25 p.m. train, and to whom I introduced, or rather pointed out, the chief actor in that very remarkable tragedy, the closing act in which a gentleman named Cateraft was requested to take a prominent part at Aylesbury on March 14, 1845. A more striking illustration of the value of the telegraph could not possibly be conceived. Williams was in private clothes, so no suspicion was aroused, and it was arranged that he should act as conductor to the bus, which he kept until it arrived in the City, when the man he was specially assigned to watch left the bus, and was followed by Williams to the Jerusalem coffee house, where, learning all particulars as to name and address of the suspected party, he left him for the night. Williams' instructions did not go further than this, as the man's apparent respectability created a kind of doubt as to his guilt. Even the deputy superintendent at Paddington (Mr. De May) remarked to Williams and myself, when I opened the first class carriage in which the man rode to Paddington, that "it was all a mare's nest," an opinion, however, which neither the jury at Salt Hill nor the one at Aylesbury thought fit to endorse.

On entering the telegraph office the following morning I received instructions to send Williams to apprehend the man whom he found at the said coffee house."

THE EFFICIENCY OF SMALL ELECTRO-MOTORS.

BY E. H. CLIFFORD.

The author gives the results of tests made at the Massachusetts Institute of Technology, by Messrs. F. A. Pickernell, H. G. Pratt, D. P. Bartlett, and himself. The experiments were exclusively devoted to the determination of efficiencies governing and smoothness of running under different loads being disregarded. The instruments used in the determination of the current and electromotive force were Sir William Thomson's current and potential galvanometers. These had previously been carefully calibrated, and found to be correct to within 0.2 per cent. in the positions in which they were used in the tests. In cases where the compensating magnets had to be used, their intensity was carefully determined on each day of use, as far as possible, however, the use of the magnets was avoided. For measuring the power given out by the smaller motors, a raw-hide belt or a cotton cord was passed completely round a brass pulley on the motor-shaft, the upper end being attached to a spring-balance, and the lower end to a scale pan. By varying the weight in the scale-pan, the speed of the motor could be changed. A Chatillon balance, weighing to 100z., was

* Abstract of paper from *Proceedings of the American Academy of Arts and Sciences*, given in the *Journal of the Institution of Civil Engineers*.

used. In the tests on the Gramme magneto and the Gramme 'small light,' the machines were placed in a cradle dynamometer, a modification of the form devised by Prof. Brackett, at Princeton, and a dynamo machine was used as a friction brake. By closing the circuit of the dynamo through greater or less resistance, the work done, and consequently the power absorbed by the brake, could be varied. For accurately measuring the speed, the speed indicator from a small siren was used. This was connected to the motor by an endless band, passing from the pulley on the motor shaft to a pulley of the same diameter as the siren. The power required to run this indicator was extremely small, and, in computing the work done, was not considered. The slip of the belt was negligible, as shown by numerous tests. With the Gramme magneto and the Gramme small-light, a continuously-recording engine-counter was used, connected to the motor by means of a flexible spiral spring.

Thirteen motors were tested, a short description, or reference to a published account, of each of which is given by the author.

The author's Table II. gives full details of the tests of the model Edison machine. The motors tested were, with one exception—the Gramme small-light machine—intended for very light work, and the efficiencies were therefore not nearly so high as would be shown with larger machines. In a paper on "Electromotors and their Government,"† Prof. Ayrton and Perry state that motors may be constructed to deliver 1 h. p. per 100lb. of dead weight. Table III. does not support this conclusion; and the author thinks that, for moderately small motors, 300lb. per h. p. would be a closer figure, although with larger motors this would be considerably reduced.

LITERATURE.

On a Surf-Bound Coast, or Cable-laying in the African Tropics. By ARTHUR P. CHOTCH, B.A. (Simpson Low, Marston and Co.)

We have read this book from beginning to end with a great deal of pleasure. It certainly possesses the great merit of "go" and liveliness, and in common with the good knife grinder, "story it has none." The book is what purports to be, a "portion of a diary written during a cable-laying expedition." The expedition was that of the Silvertown Company to lay a portion of the West Coast of Africa cables, and we may go further than this book does, in stating that the expedition was perfectly successful. Not only did it do good work in laying cables, but the expedition added extensively to our knowledge of the ocean

bed through the numerous soundings that were taken over the course in which the cables were laid.

This, the newest book about cable laying, caused us to look out and con over once more the first descriptive book on the subject, that of Dr. W. H. Russell, published just over twenty years ago, in which the concluding sentence reads: "The last word transmitted through the old telegraph from Europe to America was 'Forward,' and 'Forward' is the motto of the enterprise still." From then till now the cry has been "Forward," till the Alexanders of the cable world have joined together the uttermost parts of the earth. They may have no new worlds to conquer, but their work is far from complete. Feeding links to the main cables will be needed in every direction, and cable-laying and cable repairing will long be a field for the display of science, experience and skill. Mr. Crouch's book does not pretend to be scientific, in fact that part of the business is carefully eschewed; but it is a graphic, racy sketch of the life led during a cable laying expedition. It touches with a light, but firm hand, the life on board ship, both while waiting and while active; it describes briefly but clearly the broad peculiarities of the places touched at, and keeps up from first to last a good substratum of fun at all the surroundings, and especially the *gens homo*. Those who have had a peep behind the scenes will have no difficulty in fitting the characters of the book to individuals, although the *noms de plume* used give no clue to outsiders. As a specimen of the author's manner and lighter matter, we may quote the following, wherein Mr. Jenkins describes his first night at Accra. Mr. Jenkins was directed to the house of a Mr. Schwartz, at which in due course he arrives, coolly walks in, takes the easy chair, and commences a pipe. By and-by he is discovered by a servant, who rushes off and brings back Mr. Schwartz, who cries out:

"Who are you? What do you want? What business have you got here? Just clear out of my house!" To which I replied, not quite liking his manner, with considerable deliberation and interspersed with several puffs at my pipe—

"I am afraid there is some little misunderstanding here. My name is Jenkins. You I believe to be Mr. Schwartz; and I was told that you had kindly offered to put me up for the night."

"My name is Schwartz, but I never heard of yours before; so the sooner you move out of my house the better."

"Well, this treatment kind of roused me. It wasn't hospitable, to say the least, considering it was my first night ashore. So I said

"Mr. Schwartz, I reckon you must be labouring under some mistake. Your name was given me, this house was pointed out to me, I was told to come here, and here I am, and here I mean to stay."

"But I don't know you, I tell you."

"Well, if it comes to that," I replied, "I don't know you either. So we're level there."

"He looked at me gasping for a minute or two, and then he pulled himself together and began stamping up and down the room kicking at all the tables and chairs which lay in his way."

"This is a nice state of things! You come in here, light a pipe, seat yourself on my favourite easy chair, and positively refuse to move when so requested. You'll be ordering dinner next, I suppose. Is there anything I can fetch you?" he adds in a tone of mock servility.

"Well now, since you mention it, I should like a bottle of lager."

"Whether he felt himself wholly unequal to contend any longer against the course things were taking, or whether the mention of a favourite drink was sufficient to dispel his anger, I couldn't say, but the expression of his countenance changed and broke into a radiant smile, and turning to the nigger who was standing in the door-way, he cried

"Hie, you rascal, go and bring a couple of bottles of lager," and then he placed before me a box of cigars, and sitting down, he made himself so agreeable that I don't know if I have ever been better lodged in foreign parts than I was last night."

THE ELECTRICAL ENGINEER.

Published every Friday.

Price Threepence; Post Free, Threepence Halfpenny.

Editorial and Publishing Offices:

139-140, SALISBURY COURT, FLEET STREET,
LONDON, E.C.

TO CORRESPONDENTS.

All Rights Reserved. Secretaries and Managers of Companies are invited to furnish notice of Meetings, Issue of New Shares, Installations, Contracts, and any information connected with Electrical Engineering, which may be interesting to our readers. Inventors are informed that any account of their inventions submitted to us will receive our best consideration.

All communications intended for the Editor should be addressed C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, E.C. Anonymous communications will not be noticed.

TO ADVERTISERS.

Advertisements should be addressed to the Publisher, 139-140, Salisbury Court, Fleet Street, E.C., and should reach him not later than noon of Thursday. **Special Terms** for a series can be arranged on application.

"SITUATIONS VACANT" and "WANT PLACES" Advertisements will be charged at **THREE WORDS for ONE PENNY**, with a **MINIMUM** charge of **SIXPENCE**.

TO SUBSCRIBERS.

"THE ELECTRICAL ENGINEER" can be had, by Order, from any Newsagent in Town or Country, and at the various Railway Stations; or it can, if preferred, be supplied direct from the Office, on the following terms:

	3 months.	6 months.	12 months.
United Kingdom	3s. 3d.	6s. 6d.	13s. 6d.
Within the Postal Union	4s. 4d.	8s. 8d.	17s. 4d.
Other Places	4s. 10d.	9s. 8d.	19s. 6d.

(Post Free, Payable in Advance.)

Cheques, Post Office and Postal Orders for Subscriptions and Advertisements, should be made payable to C. H. W. BIGGS, 139-140, Salisbury Court, Fleet Street, London, and be crossed "Union Bank."

NOTICE.

With our issue of January 6 we gave a Portrait of E. GRAVES, Esq., President of the Society of Telegraph Engineers, and stated our intention of giving a series of Portraits of eminent Electricians of the century. In fulfilment of our promise we have already issued a Portrait of W. H. WOLLASTON, M.D., F.R.S., who was in his scientific prime at the beginning of the century. This will be followed by SIR HUMPHREY DAVY, F.R.S., whose fame as an electrician is still more prominent than that of WOLLASTON. Portraits of Past Presidents of the Society are in preparation, and we hope soon to have ready that of PROF. D. E. HUGHES, F.R.S.

INTERFERENCE OR COMPETITION.

The action of the Maxim-Weston Company in connection with the recent negotiations concerning the lighting of the City with the electric light has been commented on with considerable asperity and severity. The time has come when the question may be asked if such action can be justified in any shape or form by the laws which usually govern business transactions. Competition may be fair or unfair. It may be keen and sharp, yet perfectly legitimate; while, on the other hand, some methods of procedure are disclaimed by all whose ambition is to be reckoned amongst those deemed honest men. It is said that most of us start out in the world with the object of making money, to make it honestly if we can, but to make money. These words, which are so frequently heard, show that two ways of making money are recognised, one of which is by no means satisfactory. There is one way of making money that has received little attention, and which depends chiefly upon the way in which other people's money is lost. Directors of public companies are sometimes in the peculiar position of being able to make money at the expense of the shareholders. In fact there are four results which their efforts may bring about. They may benefit both themselves and the shareholders, themselves and not the shareholders, the shareholders and not themselves, or neither themselves nor the shareholders. As a rule, directors are firm believers in the policy of one of England's greatest premiers, whose greatest anxiety was always for the welfare of the greatest number, but who admitted, on being cross-questioned upon the subject that the greatest number was—Number one. A paraphrase upon the above words might be given, that it is the duty of every firm to get business, honestly if it can, but at any rate to get business. Here it seems we have the kernel of fair and unfair competition, the latter coming from those whose sole object is—at any rate to get business.

An earnest faith that, somehow, whatever is done will turn out well, and an intensely real conviction of the transcendental force of their own business capacity are the characteristics of the men whose sole object in life is to get business and to make money. They idolise the American system, wherein no moral law is tolerated, nor by which is anything permitted to stand in the way of attaining the object aimed at. We cannot say of those men what Froude says of England's forgotten worthies, "their profession was the school of their nature, a high moral education which most brought out what was most nobly human in them;" but rather we would say of them as Artemus Ward said, "There is much human nature in man."

There are two fundamental ways and two only for obtaining business; the one where the purchaser experiences a want, and of his own accord goes to

supply it; the other, and the more frequent, where the supplier has to prove to the purchaser that this want really exists. The man who has always been blind cannot of himself experience the want of "more light," nor can he who has never had the sensation of taste want "more sweetness." Others may, however, explain to the blind the advantages of light, and hence get him to experience the want, and likewise with taste. The business man, so to speak, has to open the eyes of the blind and the ears of the deaf in order to obtain custom.

Consider then the special case we have mentioned, though it is by no means the only one of its kind. The Corporation has a faint notion that there exists a want of more light, and that it can be supplied by electricity; but it required the consistent and persistent efforts of the Brush Company, extended over a couple of years, to thoroughly convince a committee of the reality for the want and ability of that company satisfactorily to supply it. So far, however, success has attended the Company. History records the lighting failures in the city, and unwritten history tells the reason of these failures. It is agreed among competent men that there is no valid reason why the Brush Company should not have successfully carried out the contract on the lines submitted to the Corporation. It is well known that the plans had been carefully matured, the details examined and re-examined, and that so far as the experience and scientific attainments of the Company's staff could suggest, they were perfectly well adapted for the purpose in view.

At the eleventh hour, the Maxim-Weston Company comes forward with a crude ill-considered scheme, and offers to perform certain work for a certain sum. Now we most distinctly, deliberately and emphatically, say that the proposed work could not be carried out for the sums which have been publicly mentioned; and we call upon the Maxim-Weston Company to justify its action by producing the detailed estimates upon which the tender was based. If the amount of the tender was so low that the work would result in a loss and not a profit—and if this was known in any shape or form to the directors—we say that they acted in a most unfair and unbusiness like manner, not only to their trade competitors but also to their shareholders. If the directors have been misled by miscalculations of their servants the sooner they acknowledge the fact the better. There is no doubt but that the damage done by the mis-timed action to the immediate progress of the industry has been very great; and if such actions are to be connived at without general condemnation the sooner that fact is known the better. Is it fair competition to wait till an opponents scheme and price are practically public before making an offer for the work? We will not say a word as to the possibility of the Maxim-Weston Company being able to carry out the scheme proposed. Let it be

assumed that no hindrances, financial or otherwise, would have been met; the question still remains whether it was fair competition to utilize obstructively another company's initiative and labour. If both schemes had been put forward together, and driven side by side, there would have been nothing to say; but it was not so, the one was not heard of till the other was practically settled. We maintain that the action of the Maxim-Weston must be repudiated by every honest trader in the country, till such time that they can show that they were called upon to formulate a scheme and to submit a tender, and prove incorrect our contention that the work proposed could not be carried to success for the amount specified in the tender.

THE PRESENT STATE OF FIRE TELEGRAPHY.

The paper read by G. R. von Fischer Truenfeld on this subject at the last meeting of the Society of Telegraph Engineers is an interesting one from several points of view. The subject is one that has been but little studied. Unfortunately the demands upon our space preclude any possibility of giving the paper fully, so that we must content ourselves with giving the conclusions of the author as deduced from the mass of statistical information examined by him. There is only one point in this paper whereon our opinions differ materially from those of the author. But first we give the author's summary as follows:—

I will now recapitulate the facts which result from the numerous official reports laid before you, viz.:—

1. Since the subject of fire telegraphy was first publicly introduced before this Society in 1877, a great general progress has been made in British towns and elsewhere in the increase of facilities for raising speedy alarms at the outbreak of fires. The time between the discovery of a fire and the appearance of the brigade has thus been considerably reduced.

2. Fire-telegraph street call-points were first introduced in London in the year 1880. They not only proved to be of great value in reducing serious fires, and thus saving property, but it also soon became evident that the fear of wilful damage to the fire-telegraphs and of false alarms being raised is not so well founded as to detract from the high value of a complete fire telegraph installation.

3. Not only has the number of alarm points been generally increased, but a limited number of British towns has already successfully adopted a system of public call-points.

4. Although a general increase of population and a consequent increase in the number of fires has everywhere taken place, the percentage of serious fires, and with it the amount of property destroyed, has, nevertheless, been generally decreased. This has been the consequence not only of a greater efficiency of the brigades, but especially of the higher proportion of alarm points to inhabitants, which, again, is identical with ample provision of telegraphic appliances and with more rapid telegraphic communication.

5. Although the number of alarm-points has generally increased in British towns, and the percentage of serious fires has accordingly diminished, these undoubted improvements have, nevertheless, not yet reached that point of perfection which they ought to attain. Both the proportion between alarm-points and inhabitants and the percentage of serious fires in British towns compare badly with Con-

tinental and American towns. Whereas in the former an average number of 27,000 inhabitants counts for each fire-alarm point, only about 3,000 inhabitants corresponds to every alarm-point in Continental towns, and even less in America.

6. As serious fires have become proportionately less, the total loss of property has not increased during the last ten years, although the total number of fires has nearly doubled. The present average loss of property for each fire is thus only about half, and often even less than half, the amount it was ten years ago.

7. The percentage of lives lost from fires has not been appreciably influenced by an increase of alarm-points. In spite of the increased efficiency of brigades and of more extended telegraphs, modern fires show a more destructive tendency, so that an increase in the percentage of lives lost is apparent not only in England, but generally. As the protection of life chiefly depends upon factors which lie very much beyond the reach of even the most efficient brigade and the most perfect telegraph equipment, the latter can only contribute in preventing a more rapid increase in the death roll from fires.

8. The inhabitants of all towns which have adopted fire-telegraphs soon became used to the electrical appliances. Thus by far the greater number of fire alarms have been transmitted by street call points and other electrical appliances, and only a very small proportion have been received verbally.

9. Considerable advantages accrue to any fire-telegraph system, and consequently to the protection of property, from the connection of such system with that of the Telephone Exchange.

From the general tone of the paper—as well as conclusion 7—we gather that Mr. Truenfeld was surprised to find the percentage death rate undiminished by the increased use of better appliances. We on the contrary should have been just as surprised to find the percentage death loss diminished. It seems to us that the use of better appliances is calculated—as was proved by the author—to lessen the average money loss per fire, and that is a great achievement. As a matter of fact, we believe, the majority of deaths are caused by suffocation, and probably, in the greater number of instances where loss of life occurs, the death takes place before the existence of the fire is known. Of course we must except from this statement fires in theatres, although again the death is here due to suffocation; but in this case the disaster is usually due to a total disregard of all provision for emptying the theatre quickly. If our contention is right, the death rate will always be proportional to the number of fires and not to the magnitude of the fires.

CORRESPONDENCE.

TRANSFORMERS.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: I had more than one reason in not giving full figures in support of my argument in favour of "transforming by means of accumulators," at the recent meeting of the Society of Telegraph Engineers.

1st. I had already written, at the request of my friend, Mr Kapp, a memorandum for his paper, and I did not consider myself justified in using the same figures pending the publication of that statement.

2nd. I prefer to bring these figures forward in a paper of my own, where I should have the right of rejoinder

after they have been thoroughly criticised by others. I am, perhaps, aware that I intend to deal with the subject in a paper I am to read before the Society of Arts in 1889, and I trust that the council of the Society of Telegraph Engineers will be able to find room for a short paper on the same subject during the present session, so that every one interested in the subject will have ample opportunity of criticising my figures, and forming his judgment thereon.

Yours, &c.,

R. E. CROMPTON

Mansion House buildings, London, E.C., March 12, 1888.

FIRE OFFICE RULES.

TO THE EDITOR OF THE ELECTRICAL ENGINEER.

SIR: At length the blow has fallen, and we have another set of Fire Insurance rules!

We have to-day seen a copy, and we presume that not only will the telegraph engineers get out a set, every individual insurance company will follow. What contractors to do then: what will the public think? If the society had only been content to adopt the known Phoenix rules, and embody them as their own (and course acknowledging their origin), all this trouble would have been averted.

Who can tell the amount of damage that will be done to our industry through the obstinate and irresponsible action of our presumably representative society?

If a poll had been taken of the society's members, the electrical trade, would not the verdict have been in favour of letting well alone, and giving to the Phoenix rules (which certainly have the merit not only of price but of secured success) the authority of the telegraph society?

These are burning questions, and certainly require immediate attention of every

ELECTRICAL CONTRACTOR.

ELECTRIC MOTORS.*

BY G. A. LEIBIG, JUN.

The development of the electric motor from its primitive up to its present state of advancement and usefulness has been similar to the growth of nearly all of those great discoveries which have proved themselves at first so adaptable and necessary to the wants of everyday life.

The history of the motor is a very remarkable one, not as a story of rapid improvement, but also because its first steps belong to very recent times.

We can now ask ourselves, not without astonishment, what happened, seeing that the laws of the conservation of energy were so generally accepted that the reversibility of the dynamo and motor was so lately discovered. It is quite true that the first motor was built many years ago, but for a long time after the dynamo had undergone many marked improvements the motor was not turned to practical account. In other words, dynamos and motors have all along been kept distinctly apart, and even to day there exists sometimes a certain indefiniteness about their relation.

We now know that the general term "Dynamo Electric Machine" includes not only generators of electricity but appliances for converting electricity into other forms of energy, and that all the mathematical formulae which have been applied to the dynamo as a generator of electricity are equally applicable to the dynamo when viewed as a source of motive power. Only changes necessary in any formulae relate to the algebraic signs of certain symbols.

The feature of reversibility is of extreme importance, means that any rule of construction or of design that would make a dynamo machine an efficient apparatus will give identical results when used in connection with motors. Other considerations may present themselves, questions of speed and output, unit weight of material may arise, and these may be different in the two cases, but they are of a mechanical, or at any rate, of a secondary interest, and in no way affect the mathematical considerations. In what follows, therefore, we shall use the term "dynamo electric machine" to designate, unless otherwise specified, either a generator of electricity or a dynamo reversible as a motor.

In order to give an intelligible review of the work which has been done on dynamos and prepare the way for a few considerations which will follow, it may be well to describe briefly

* Paper read before the National Electric Light Association, Edinburgh, Feb. 21-23.

component parts of a dynamo electric machine, and refer to the purposes for which they are intended. In every dynamo we must have a continuation of the following elements —

(a.) An iron body or framework constituting the magnetic limbs. This is always wrapped over a certain portion of its length with insulated copper wire, and its purpose is to produce between its ends or polar surfaces a region of magnetic force.

(b.) A series of coils of copper wire, generally wound upon a subdivided mass of iron, and capable of revolution about an axis in such a way as to make each coil pass successively before the polar surfaces of the magnetic limbs. This is called the armature, and is always so placed that it helps with the magnets to form a nearly closed magnetic circuit of iron.

(c.) A commutator, which is merely the projected ends of the armature coils, and which, revolving with the armature, effects a continuance in the direction of the currents formed alternately plus and minus.

(d.) Several brushes or collectors, usually two in number, consisting of pieces of metal which press upon the segments of the commutator, and which are in metallic communication with the terminals of the machine.

In general, the armatures revolve between the poles of the electro magnets, but in some machines, notably those intended to furnish alternate currents, the armature is stationary and the magnet coils themselves revolve. This is, however, immaterial, inasmuch as what we have to consider is the relative motion of the parts of the machine, not their absolute movements.

It appears, therefore, that the dynamo machine, since it contains, broadly speaking, of an electro-magnet and a revolving coil of wire is a very simple piece of machinery, yet it has taken years of hard labour and patient investigation to evolve from the spinning disk of Faraday the dynamo of to-day. There is a feature in the history of the dynamo which must appear remarkable to everyone thinking of the subject. When we remember how much attention has been directed to dynamo machines, not only by practical but also by scientific men, and recollect that all the materials for a complete theory of the dynamo have been for several years at hand, we are inclined to wonder at the absence of such a theory. Even to-day no complete theory exists, though we are in an immeasurably better position in this respect than we were five years ago. For what we now know, in so far as it is immediately applicable to dynamos, we are mainly indebted to the labours of Clausius, Hopkinson, and a few others. It is sometimes claimed that the theory of the dynamo has been seriously crippled by the want of sufficient knowledge regarding the law of electro-magnets, namely, the law connecting magnetic force with the magnetism thereby produced in magnetic bodies. If we admit that an empirical formula is required we must admit the justice of the claim, because no accurate expression of this kind has ever been originated. But we shall see that is by no means necessary to depend upon empirical laws, all that we require are the causes of magnetisation, and these have been before the world for some years. However, we now possess the results of a new series of investigations on magnetisation and magnetic permeability undertaken at home and abroad, among which the most important are those of Hopkinson, Ewing, Rowland, Waibling, &c. These results, in connection with the work already referred to, make it possible to calculate to a close approximation—at least for certain forms of machines—just what any given dynamo will do when we know, besides its dimensions and configurations, the kind of iron used in its manufacture.

The word magnetic permeability, used above and which enters so frequently into dynamo calculations, is defined by Maxwell (Vol. 2, p. 50), as the ratio of magnetic induction to magnetic force. It is also called magnetic inductive capacity, corresponding with specific inductive capacity in electrostatics. Following out an analogy in a different direction, it sometimes happens that magnetic permeability is called magnetic conductivity, or resistance, the idea being to express the varying resistance offered by a given body to the production within it of "lines of induction," just as the lines of flow are opposed by a porous solid, through which is forced an incompressible liquid. Further, we know (Maxwell, Vol. 2, p. 51) that the magnetic induction is related to the magnetic force in exactly the same way that current is related to electromotive force, namely, we have:

$$B = \mu H \text{ and } C = R E,$$

when μ is the permeability, and R the conductivity. But the analogy is in a sense imperfect, for whereas R (conductivity) is a constant, in so far, at least, as it is absolutely independent of the current flowing (leaving all heating effects out of consideration), the permeability is by no means a constant, but depends mainly upon the present state of the material in reference to the induction within it, but also upon its previous "magnetic history." Thus it is a variable quantity, and, for magnetic bodies, grows less and less as the magnetising force increases. We can, therefore, regard the analogy between B and H on the one hand, and C and E on the other, as holding good only when H is a very small quantity.

In the calculations applied to dynamos it is extremely important to know the distribution of magnetism and the polar surfaces of the electro-magnets, that is, the number and direction of the lines of induction from pole to pole. A solution of this problem can be arrived at mathematically in an approximate way only, and then, as a rule, by the consideration of what takes place in the least complex forms of surfaces. To attain certain ends the graphic method may be applied either roughly by the use of iron filings or more carefully by the employment of a small magnet suspended by a film. By observing the positions assumed by this small magnet, when fully suspended in different regions of the magnetic field, we can form some idea of the form of the field. For we know that the direction given by the magnet coincides with the resultant direction of the magnetic force at that point (the needle being supposed so small as to exert no disturbing influence), and also that the relative number of lines of force in a small space surrounding the point measures the relative field intensity. The positive directions of the lines of force may be taken as from the north pole to the south pole, both outside and inside the magnet, and they are related to lines of induction in this way. Outside the magnet they coincide, inside the magnet they are in opposite directions. This amounts to saying that the lines of induction are continuous, whereas the lines of force are not.

Other methods of measuring the field intensity of dynamos have been proposed, such as the magnetometric method. The results so obtained are, however, inaccurate; and, indeed, the method cannot be applied at all when the armature is in place. Nor can the very simple pendulum method devised by Sir Wm. Thomson be applied, because the air space between the armature and magnets is too small. It can, of course, be used by removing the armature, and it has the advantage of giving results directly in absolute measure. Unfortunately measurements obtained under these circumstances do not give us a reliable basis for calculations, inasmuch as the form of the magnetic field is strongly influenced by the presence or absence of the armature, at least when it contains iron. It may be remarked that magnetic distribution is exactly analogous to electric distribution, especially in the case of dielectrics, and that the geometric form which influences the latter plays almost as important a part in the case of magnetic distribution.

We are well aware that the density of electricity in a given portion of a charged body depends upon the shape of the body, and also upon the presence near it of other charged bodies. The same laws of surface densities determining the so-called leakage of lines of force obtain in the case of magnetism. In almost all dynamos the pole pieces have necessarily somewhat sharp edges, and the number of lines of force per unit area is greater at the edges than on the remaining polar surface. This number is subject to a change when the armature is in place, and to a further modification when the armature revolves, on account of the changes in the direction of the axis of magnetisation of the latter.

These considerations show us that any system of measurement which will give useful results must be of such a nature as to be applicable to the dynamo when in working order. The ballistic method fulfils these requirements, it is sufficiently accurate, and, moreover, involves no special difficulty. We have simply to surround that part of the magnetic circuit of which we want the induction, with one or more turns of copper wire connected with the ballistic galvanometer, and observe the throw of the galvanometer needle when the magnetism is reversed or reduced to zero. It is always better to observe the deflection of the galvanometer needle due to a reversal of magnetism. An uncertainty always attends a reduction to zero, owing to the phenomenon of residual magnetism. The galvanometer having once been calibrated in absolute measure, we can, from the throw of the needle, calculate the value of the total induction within the wire, and the magnetic force is known from the data of magnetising current and number of revolutions. The experiment is repeated for the different parts of the machine, so that we finally obtain the values of the induction throughout the entire magnetic circuit. Suppose, now, we have measured the field intensity, and have a value of the induction per unit area, we can then, by Faraday's law, calculate the electromotive force which would be set up in a conductor moving in any manner in the field. The law is this: The E.M.F. produced in a conductor moving in a magnetic field is equal to the rate of cutting the lines of force. If the conductor forms a closed circuit, the E.M.F. depends upon the area of the circuit. Hence, in order to be able to determine the E.M.F. produced in an armature, we must know the mean area of the coils of the armature, the strength of the magnetic field, and the velocity of rotation.

Call N the total number of lines of induction (flow of force) passing through the armature, and p the current; then we have for the force X acting when the circuit is displaced through the distance dx , by the principle of the conservation of energy (Maxwell, vol. 2, p. 137):

$$X = -p \frac{dN}{dx}.$$

I. Heating of wires equal to

C²R or E²R.

II Foucault currents in pole-pieces. This depends upon number of armature section (\propto fluctuations of current), and is generally small, unless the Pacinotti form of armature is used.

III. Foucault currents in armature. This depends upon strength of field and in the modern laminated armature may be neglected.

IV. Reversals of magnetism of armature equal to $\frac{1}{2} \pm$ Cossin π free \times maximum induction \times $\pi \times$ volume.

That is, it depends upon (strength of field)² and velocity of rotation. No amount of subdivision of armature coil can affect this except in so far as it modifies the total volume of iron in the armature. However, a low magnetic resistance is necessary, and to secure this the armature must contain much iron. It is on this account that an advantage from a stationary armature coil would be derived.

V. Momentary short circuiting of armature coils, depending upon coil of coil and mutual induction of armature coils and strength of field.

VI. Finally. Friction in bearings. This is difficult to estimate. If the belt is such that Mair's principle holds true, losses due to friction are constant.

In regulating motors the speed is constant, or nearly so, hence the causes of the dissipation of energy are confined to variable currents in the conductors and to changing field strength. These in compound wound and constant current motors depend upon the load, but as we see at once are practically constant for a properly made shunt machine. For a pure shunt machine, therefore, the efficiency, provided the speed does not change, is independent of the load.

Before bringing to a close the few remarks which I have ventured to make on the subject of electric motors, it may be interesting to give a few facts regarding the growth of the motor industry, and point out how various are the demands made upon the machines for manufacturing and commercial purposes.

Through the kindness of the Executive Committee of the National Electric Light Association I am enabled to bring before you a few figures, which will, I trust, act as an incentive to increased activity in this direction.

The committee has addressed circulars to 234 companies engaged in electric lighting, with the following questions.

- I. Number of motors in operation.
- II. Size of motor.
- III. Maker's name.
- IV. Current used.
- V. Charge per h. p. per month.
- VI. Charge per month per arc and incandescent lamp.
- VII. Results as to service.
- VIII. Consumers' opinions as to power and service.

As a result, answers have been received from fifty-six companies, and from these replies the following statements have been gathered—

Average charge per h. p. per month, 10 hours' run . . .	\$10 00
Average charge incandescent lamp, 10 hours' run . . .	13 50
Average charge per arc lamp till 10 o'clock	9 83
Average charge per arc lamp until 12 p.m.	13 00
Average charge per arc lamp all night	22 00
Highest charge per h. p. per month	15 00
Lowest charge per h. p. per month	6 25
Highest charge per incandescent lamp per h. p.	21 00
Lowest charge per incandescent lamp per h. p.	11 25

The motors supplied with current have been used for the following purposes: Driving ventilator fans, collar and cuff machines, printing presses, various apparatus in repair shops, sawing machines, coffee mills, machines in gum shops, sausage machines, elevators, lathes, pumps, saws, ice-cream freezers, organ bellows, appliances in laundries, &c.

Sizes of motors have varied from $\frac{1}{2}$ to 15 h. p. Twenty-six companies have supplied motors from arc light circuits, 14 from arc and incandescent, and 16 from incandescent lamp circuits alone.

In 34 cases subscribers own motors and pay per month for current, in other cases companies own motors and charge rental for same. Companies are endeavouring to have subscriber's own motor in all cases and pay for current. Electric light companies are satisfied and willing to enlarge the business. Consumers' reports are also very satisfactory.

Although the number of cases cited above is small, it is still enough to show us how effectually the motor can supplant the steam engine, especially for those purposes for which the power required is small and under complete control. The opinion of those who have used electric motors indicated that they do their work well, and encourages us to expect a brilliant future for this branch of applied electricity.

ALTERNATING CURRENT ELECTRIC MOTORS.

BY DR. LOUIS DUNCAN.

(Concluded from page 243.)

What seems to me the simplest, cheapest, and most efficient means of running alternating current motors is this: build the motor on the same general plan as the dynamo, with such modifications as the different conditions of working impose, and start it and excite the field magnets from a continuous current circuit, run with our alternating circuit, supplied with current by a dynamo at the central station. If we wish to distribute 500 horse power our continuous current should have a maximum capacity of about 50 horse power. To start the motor we should have the following arrangement: there should be two breaks in our armature circuit, one between the regular brushes of the machine, the other at a commutator for the continuous current. At this second break the two ends of the circuit should be taken to alternate bars of the commutator, the number of bars being such that the direction of the current is reversed every time a coil passes a pole. The alternate bars are normally connected by a metal ring pressed against them by a spring; in this case we will have the normal circuit just as if there were no continuous current commutator. On the motor would be a switch-board that would accomplish the following things: If we wish to start we turn the handle of the switch to a certain position, this will short circuit our regular brushes and by the aid of a couple of levers will drop the continuous circuit brushes on the commutator, at the same time pulling away our metal ring. The motor will then start as a continuous current motor; when it has reached its proper number of revolutions or is above it, turn the handle a little further; the continuous current brushes will be raised, the metal ring will connect the commutator bars, and the alternating current will be made, and the motor will continue to run and will do work.

Now, I consider that the advantages of this plan are these. It makes the motor simple and cheap to build; it will be more efficient and have a greater output than the other motors that have been discussed; the currents to excite the fields will have to be supplied anyhow, and they cannot be supplied more economically than from the central station; being simpler there will be less liability of derangement.

The motor described by Professor Thomson that I mentioned above, consists of field magnets, through which the alternating current flows, with an armature not in any way connected with the external source of current, but which has currents induced in it just as if it were the secondary of a transformer. The currents of all the armature coils are open, excepting one that is in such a position that the current induced in it will be repelled by the pole-pieces. In this form I do not think the motor will be particularly efficient, or give any considerable output. It is possible that the principle may be further developed to give a considerable output, but I do not believe that any motor in which the field is fed by alternating currents can be cheaply made, although this is a matter of which I have no experience.

To prevent motors stopping when the load is thrown on it would only be necessary to drive the band from a friction pulley on the shaft of the motor. The pulley should be so adjusted that it will turn just before the motor falls behind its point of its maximum work.

It is possible that all of the plans I have suggested have been tried by the different inventors who are at work on this subject. If a motor of each type that I have mentioned were built, and proper experiments were tried upon them, we would—provided we had the ability to interpret and apply our results—have the data necessary to design the best possible machine of each type, and if we build these it would settle the question as to which form will be the best. There is no necessity in building an indefinite number of motors to experiment with. It is too much the custom, if we wish to design a dynamo, for instance, to build twenty different ones and see which is best. One machine, with proper experiments and deductions, should put us on the right track.

Dr. Holmes once said that when he had written anything that pleased him it immediately seemed very old indeed. I, with humility, feel much the same way, as if what I had said this evening is so apparent that every one must have known it. I can only hope that some of the suggestions I have made will help the development and final successful application of the alternating current motor.

DISCUSSION.

Mr. Wolcott: I have been very much interested in Professor Duncan's paper. It throws rather a different light upon the subject of alternating motors from the paper of Mr. Stanley. From the latter paper we concluded that the alternating system, all the way through, was slightly more economical than the direct. But Professor Duncan has shown, I think, pretty conclusively that there are various losses there which we do not have in the direct system. The loss from heat, which depends upon the square of the current, I think is very neatly demonstrated the work depending on the product of the current and the electromotive force changing in sign whenever the

electromotive force changes, while the loss in heat is constantly plus because the square of the minus quantity is plus, as well as that of the plus quantity. There is one advantage, I think, in the alternating system which is entirely of a practical nature, irrespective of the efficiency, and that is that you do not use any commutator at all. I know one of the greatest practical difficulties in both motors and dynamos is the trouble of having a commutator. If there is any possibility of running a street railway with an alternating motor I think it would be a great advantage, even if it was not so economical.

Mr. Mailloux: I would like to remark with reference to the application of alternating currents to the purposes of electrical traction, as my friend Mr. Wolcott suggests, that it will probably become time before we succeed in utilizing it, however great may be the advantage of its use; because the alternating current motor fails to afford one of the chief requirements demanded in a motor for electrical traction,

FIG. 9.

namely, capacity for producing great torque or effort at the periphery of the armature at the time of starting. This is exactly what the alternating current will not do. Dr. Duncan has pointed out the necessity for gradually putting the load on, so to speak; while, as we know, in electrical traction, it is necessary to develop large pulling capacity or effort.

Mr. Crocker: There are two or three practical points that suggest themselves to me. In the first place, Dr. Duncan speaks about the great cost of a laminated field, and he speaks of it as if it were practically a bar to the use of laminated fields. If I were going to make a wrought iron field, or if I were bidding for a contract to make wrought iron fields, I would prefer to make them laminated rather than of forging or any other form of wrought iron that I have ever come across. So far as I am concerned, I prefer the laminations. I have been experimenting somewhat myself in this direction and was quite pleased with that feature of the alternating current motors, viz., that they do involve laminated fields. Then the other point, about putting on of a load suddenly. That is a difficulty no doubt, and a serious one, but still it does not go on with the mathematical suddenness that Dr. Duncan speaks of, I think. The belt will squeak and the load will gradually come on, and in ordinary cases, where the load is great, but not very great, it will come on gradually, the motor will take it and, I think, will run along with it. Of course, that is a question of degree; in some cases it would, in some cases it would not. But I think you could arrange that by avoiding the introduction of alternating current

FIG. 10.

motors where they had to suddenly take a heavy load, and that would be, of course, a limitation. Then as to the objection that Mr. Mailloux brought up, he spoke merely of one particular kind of alternating current motor, whereas Dr. Duncan enumerated four. I do not remember the classification very well, but I think Mr. Mailloux's objection only applies to one or two of the four classifications. The other two would be entirely outside of Mr. Mailloux's objection.

Lieut. F. J. Patten: Dr. Duncan has shown us that the curve of counter electromotive force has a variable position with respect to the mean, i.e., oscillating from side to side, and I wish to ask whether any such oscillation takes place or not provided the motor is running under a constant load.

Dr. Duncan: I think the oscillation certainly would take place no matter what load is on the motor; because in a part of every period—and a period takes place every one three-hundredths of a second—the motor is not a motor at all, it is a dynamo. That is, it is absolutely putting current into the main line. The only way to get the energy and throw that current into the main line is by decreasing its speed and drawing from its energy of rotation. Therefore, where it is in

those areas it will slow down in speed. Where it is in the larger areas it will increase its speed. But the oscillation will occur whether the load is constant or not.

Mr. Crocker: As regards the regulation of motors and the point that Mr. Mailloux brought out, it happens that one form of alternating current motor that I have been working on lately is particularly well adapted to being regulated. One of the most desirable means of regulation in any motor cannot be used in an ordinary direct current motor, on account of sparking, that is, the shifting of the brushes. When we reverse a motor by shifting the brushes, I mean shifting them right over, at first it would pass through the point of maximum sparking and would create a very serious trouble there, even when we reduce the power. It happens, as I say, that one form of motor works in exactly the other way, and that as you decrease the power you decrease the

FIG. 11.

sparking, and when you reverse it there is no sparking at all. Therefore you can regulate it in that way, which is just the way everyone would like to regulate motors if he could.

Lieut. Patten: I have designed a form and made some elementary tests of a motor of the kind suggested by Prof. Elihu Thomson in his paper read before the Institute last spring. I have always regarded Professor Thomson's motor with a great deal of admiration. It would seem from some of the discussions we have listened to that whatever work we are going to get out of an alternating system must be a question of difference between two factors opposed to each other—the self induction of the current and the power generated as well as the heating. Inasmuch, as all our results must be due to the difference between the two quantities, I have worked upon that line, trying to give that difference its greatest possible chance to do some work. If you will remember, Professor Thomson's motor as Dr. Duncan has explained it to-night, consists in a fixed field and a revolving armature, the current of which was closed when it came into position of action; at that point the current is momentarily closed.

Fig. 9 illustrates this principle. S is a solenoid with a soft iron core I, and D is a closed circuit of high self inductive capacity, per-

FIG. 12.

ferably a copper disc. When alternating currents are sent through the coils of the solenoid S, and the centre of the disc D is not immediately in the prolongation of the axis of the solenoid, there is a tendency to separate, as indicated by the two arrows. As in all forms of alternate current dynamoelectric machinery the effective action is always due to a difference between two unequal and opposing actions, so in any machine in which the principle thus described finds application the rotary torque or moment of rotation will be due only to a difference of two efforts, as shown in the preceding analysis, and the machine here illustrated is a simple mechanical arrangement of parts, the purpose of which is to cause this tangential effort, however small, to work at a possible maximum of advantage. Those who recall the forms of machine illustrated in a former lecture and based upon this principle will remember a form of machine not differing widely from the ordinary direct current machine. The armature placed at the centre of the machine consisted of a number of coils of high self inductive capacity, the different currents of which were closed in succession as they arrived in the position of maximum repulsive action. In the machine I have designed the application of the same

principle is reversed with the apparent effect of producing a more continuous rotary effort as well as a greatly increased moment of rotation by virtue of placing the point at which the effort is applied further from the axis of rotation and thereby giving to the force at work a lower lever arm, a much greater lever arm. Figs 10 and 11 are end and side elevations of the machine, and Fig 12 is a diagram of the parts and connections. A polygonal frame F F F is connected by radial strips N N, and all is supported upon the base B B. Secured to the lateral strips N N are two sets of copper discs D D and d d. These discs constitute the armature of the machine; they are arranged symmetrically, as shown, fixed to the frame structure, and consist of disks of high inductive capacity that remain permanently closed.

A spindle *s*, Figs 10 and 11, carries a revolving switch C¹², or commutator, which is secured to the spindle and turns with it. This commutator constitutes one terminal of the machine, while an insulated ring *b* *s*, and its contact brush secured to the support P P, constitutes the other. Under each set of discs, D D and d d, and secured to the spindle *s*, is a set of solenoids. The end of one set being placed at an angle of 45 degrees to those of the other set, from which it results that these two sets of solenoids will each combine alternately into action with respect to its own set of copper discs. Each set of solenoids has its four coils connected in series and the two sets are arranged in two independent circuits. Both have one terminal secured to the contact *b* *s*, and the other terminal to the alternate segments of the revolving commutator. This system of connections is shown in Fig. 12, in which the eight part commutator is shown with alternate segments connected to each other in separate series. The coils S¹, S², S³, S⁴, form one set of revolving solenoids connected in series from the rubbing contact *b* *s*, which forms one terminal of the machine, to the commutator segment C¹, and thence to all the odd numbered segments. In like manner the other set of solenoids S⁵, S⁶, S⁷, S⁸, are similarly connected in series to all the even numbered segments, C², C³, C⁴, C⁵. From this arrangement it results that, as the spindle revolves, carrying these solenoids as a sort of fly wheel, the alternating current will be sent in rapid succession through one set of solenoids, and then through the other, and by simply placing this commutator upon the spindle it can be made to send the current through the different set of solenoids during the periods of maximum effect of repulsion between each set and its corresponding set of copper discs.

The moment of rotation is evidently a maximum under this system of construction, and by increasing the number of sets of solenoids that work each other in action, the effort of the rotary torque may be made nearly continuous and constant.

It is evidently not contemplated that this motor shall drive horse power. Its efficiency is not high and its form renders such an application quite impossible, but it can find a place in the smaller industries, where light motors of a definite requirement, and render an alternating current almost a paying one during the working hours of the day.

Mr. Duncan in conclusion, replied to some of the points brought up by the various speakers.

ZONE OF MAXIMUM INTENSITY IN ARC LIGHT.

According to the report upon arc lights of the Committee charged with the photometric tests of lamps shown at the last Antwerp Exhibition, if S equals the mean spherical luminous intensity, H = the horizontal luminous intensity, and M = the maximum luminous intensity, there exists between these three quantities the relation $S = \frac{H}{2} + \frac{M}{4}$.

This empirical formula gives in most cases values which do not differ materially from those determined by exact calculation. The mean intensities of luminosity in each of the two hemispheres are fairly represented by $\frac{H}{4}$ for the

superior hemisphere, and by $\frac{H+M}{4}$ for the inferior hemisphere.

The zone of maximum intensity of light is the surface of a cone having the arc for its apex, and generated by a plane, one edge of which coincides with the vertical axis of the two carbons, the other edge making with this line an angle of about 50 degs. It is to be understood, of course, that this zone of maximum luminous intensity, is limited to the lower area of the conical figure thus described. This determination applies more particularly to arc lamps supplied by continuous currents.

Paris Exhibition, 1889.—We would remind intending exhibitors in the British Electrical Section of the meeting convened by the Society of Telegraph Engineers and Electricians for Monday next, 19th inst., at 3 p.m., at the Institution of Civil Engineers, 25, Great George street, Westminster. We believe that Mr. John Aylmer, the Society's representative in Paris, is coming over expressly to afford any further information that may be required by those who contemplate sending exhibits.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

DISCUSSION ON MESSRS. KAPP AND MACKENZIE'S PAPERS ON "TRANSFORMERS."

(Continued from page 255.)

Captain Cardew said he thought the chief theoretical novelty in the paper was the method given of making allowance for the power lost in heating iron cores, the difficulty of which was that this loss of power affected to some extent the angles of lag, and unless they could allow for this the electrical power supplied could not be exactly computed, except, perhaps, by watt meter. The assumption was that hysteresis produced an inductive effect always additive to that in the secondary coil, and if there were a true molecular friction this might be the case; but surely this was not the whole of the molecular forces, and the molecular forces as a whole opposed magnetisation and helped demagnetisation, while the friction alone opposed change of magnetisation. His ideas were probably very crude; but he looked upon a molecule of iron under cyclic changes of magnetisation as a straight spring bent first one way and then the other out of its natural position. When you bent it there was opposing force, most of the energy was stored up and given out as the spring returned, but some was lost in friction. The risk to life from the use of the alternate transformer system had been the subject of anxious consideration, and, apart from any question of Government interference, it was certain that any serious accident would materially check the progress of the system. The risk could not be considered chimerical. They had in a transformer two conductors had in close contact with each other, and with an iron core, and they were necessarily thinly insulated. One of these conductors might acquire at times any potential difference up to 2,000 or up to 2,400 volts over the other. He need not point out to this meeting that in the primary circuit, taken as a whole, there was certain to be a resultant leak. The other conductor had also its resultant leak, and this was likely to offer a resistance of not many thousand ohms. They had here what would be recognised by all who had worked much at cables and condensers, conditions favourable to an eventual breakdown. Seeing the obvious importance of some safeguard, he had waited in vain for its being brought forward, and he eventually attempted a solution himself, with a result they saw here—[pointing to an exhibit]. This iron box was a trap for leakage. This piece of aluminium foil—not platinum, as Mr. Kapp said—the lightest, not the heaviest metal—is what they might call the bait. It consisted of two round discs, separated by a narrow portion. This was laid flat in a shallow depression in the bottom of the box, which prevented any lateral displacement. There was also an insulated wire, which was just over the aluminium, and it was connected to a piece of very fine wire, which supported a spring. The box was connected to earth. The distance of the insulated disc could be adjusted by means of a screw. There was also a little disc which told them the distance at which the insulated disc was above the aluminium foil. This insulated disc was connected to any point on the secondary circuit through that piece of fine wire. Should the secondary circuit ever acquire a potential differing from the earth by more than whatever volts the safety device was set for—anything from 500 upwards—the aluminium foil was drawn up by the ordinary static attraction until it was in contact with the disc attached to the fine wire. The instant it was in contact with the disc of course it was repelled, but while in contact it had completed the circuit, and an arc would follow it, which, of course, quite instantaneously fuses the fine wire. As soon as the fine wire was fused, down came that spring and short circuited the primary circuit, causing the double pole cut-outs to operate. He had here one of these little foils which had been used several times over. It was so little injured that it had been used again and again. It had stood an alternating potential of 2,400 volts. Professor Ayrton suggested these things were not necessary, because it was so easy to connect a secondary circuit to earth. That, of course, had occurred to a great many people. If they connected the secondary circuit to earth, at any rate it was all right for the customer. But putting the secondary circuit to earth insured that as far as the secondary circuit went, there was no insulation, and consequently it practically did very much increase the strain on the insulation between the primary and the secondary circuit. Mr. Kapp described another device which had the same objects; he would only say, as a customer, he should be quite satisfied with it. As a maker of transformers, he should take it as a boon, because he should expect there would be a considerable demand for transformers. As a supplier of light, he should rather object to it.

Mr. A. Bernstein said he would confine himself to a very few questions and those only in which he felt naturally most interested. One of these was that of putting transformers either in series or parallel. In a system of transformers, where they used high-tension alternating currents, the question of insulation became a very serious one, as they had just heard from Captain Cardew. If they used transformers in parallel, they were obliged to use two main conductors between which there was a very high difference of potential, say 2,000 volts, and they were further obliged to put them very close to each other in order to prevent induction on other wires. This made the insulation exceedingly difficult. Where they had transformers in series they only had the highest difference of potential at the Lyra end of the circuit, and they reduced the difference of potential constantly on their line, so that the mean difference of potential was only one half as much, and from the theoretical point of view one would say the tendency to produce a leak would only be a quarter as large. This, of course, was a very serious matter in the insulation of these conductors, but in addition to this the matter became of far more importance, even in the transformer itself. In a transformer on a parallel system they had the same mean differ-

once of potential of 2,000 volts between the ends of the coil, and as they could not use very heavy insulation in these coils if they wanted to have an efficient transformer, there was only a certain liability of leakage taking place. In a series transformer this difference of potential might be reduced to 50 or 100 volts, or just according to circumstances, and that enormously reduced the tendency to produce any leakage. Those were two very important advantages which the series system had over the parallel system, and they were so very important, as he said before, because the question of insulation in a transformer system was one which offered a good deal of difficulty. He would now turn to another point. That was the device to prevent the current going from the primary into the secondary. First of all they would see at once that where there was a tendency to short circuit the primary with two thousand volts there was a tendency to heating. That destroyed the insulating material between the primary and the secondary, and there was a leak. The device of Mr. Kent might work very well, but it might, at the same time, do a great deal of harm if proper precautions were not taken. In using such devices as that of Mr. Kent proper precautions must be taken not to give the current a chance to leak from the primary into the metal plate, and from there into the earth.

Mr. Atkinson (of Halifax) said the few remarks that he would make referred principally to Mr. Mackenzie's paper. Mr. Mackenzie said that the great improvement of the last year or so had been the introduction of iron into the armature. He quite agreed with Mr. Mackenzie that the introduction of iron had been a great advance, but the mistake seemed to have been made of attempting to work the iron to the same degree of saturation as had been attempted in direct current machines. The builders of the multipolar disc dynamos had found by experience that with more than six poles, at all events, there was great difficulty in keeping down the heating of the iron in the armature, however well it might be laminated. A short time ago he roughly made a calculation (taking that as a basis of how many lines of force they might take in an alternate current machine without danger of heating from magnetic hysteresis. Thus assuming that a six-pole machine running at 600 revolutions with (taking Mr. Kapp's system of figures) about fourteen lines to the square inch, which he believed was about the maximum, they could work a machine of that size and speed, then with a sixteen-pole alternating machine at the same speed, and assuming there to be no greater hysteresis from viscosity, they could not use more than about nine lines to the square inch to produce the same amount of heat. That pointed at once to a considerable reduction in the density of magnetic lines to be used in alternate current machines. In the machine which Mr. Mackenzie had described he placed alternately six in primary circuits separately excited, and similar coils differently wound formed an alternating circuit. Now it appeared to himself that in working this there would be produced equally in both of those coils an alternating electromotive force, and therefore, unless the machine was excited by a series dynamo, or some dynamo with considerable self-induction about it there would be a very large alternation in the exciting circuit, and as, generally speaking, continuous current dynamos were not constructed to stand that it would produce rather a curious effect. He did not know whether Mr. Mackenzie had practically discovered that, or whether he had had any practical difficulty from that fact. He had brought there a photograph of the Comenaght dynamo (shown) designed by Mr. Kapp, and constructed by Messrs. Goulden and Co., for producing alternating currents, which had iron in the armature. That particular machine was for 2,000 volts, 30 amperes, 600 revolutions, and weighed 2½ tons, which was about 90lb. to the unit, which was a pretty fair result. The armature was a large hub of cast iron or steel, on the rim of which was wound iron tape. On the other side of that was carried an iron wire that is, because the magnets came over the top so as to laminate in all directions at right angles to the lines of the core, which was all securely riveted through, and they would see, coming through the hole there, driving spurs round the wire. The magnet ring was 40in. in diameter. There were 16 pairs of poles, and the speed at which it ran was 600 revolutions. That the thing was mechanically good was shown by this fact, that when it was running at about 1,500 volts, and at its full speed, it was accidentally short circuited, which pulled up the engine, and gave the engine a considerable shock; but there was no damage done to the armature, and no wire shifted in the slightest degree. That was a pretty severe test, because the armature had a very low self-induction. Mr. Kingston called attention to his machine as possessing this advantage that he could attach these inductors direct to the fly wheel of an engine. He, himself, did not know what Mr. Mackenzie's experience with the owners of engines was, but he thought for one owner whom he would get to allow him to attach this kind of thing to the fly wheel he would get about a hundred who would put on a pulley and would drive a machine that was going at another speed and could be conveniently put at any place they required. Moreover, he himself admitted the advantage of using a larger number of small machines, rather than one very large machine, which, in the case of a breakdown, would totally collapse. Further, a good deal had been made of the point that in machines of the class shown on the wall, what they might term the armature circuit (that is, the circuit which produced the current) was not moving, and that, therefore, the circuit might be coupled in parallel or series, as the case might be. He did not think anybody would attempt to alter the coupling of a machine of that kind giving 2,000 volts while it was running. Generally speaking it was only for experimental purposes that a machine of that kind was required.

Prof. Fleming said that he should like to describe some experiments that he made in 1885 in a couple of Ziperowski transformers, which were brought over and exhibited at the Inventions Exhibition. In that year Mr. Ziperowski brought over two of his now well-known fishery shaped transformers, and he placed them in the Inventions Exhibition, and he took the opportunity to make some experiments upon those transformers. He might mention that the transformers

were wound in order to be arranged in parallel, and that they were worked from a self-exciting alternating current machine at some distance away, and in order to give the opportunity of seeing how this system adapted itself to the transmission of energy over great distances they placed the alternate current machine as far apart from the transformers as convenience would permit, and he believed that those transformers were a thousand feet away from the alternate current machine. Each of those transformers was intended to work a full load of 200 16-candle lamps, and they were connected by a No. 10 wire with the machine. He might mention that the primary current was operated by an electromotive force of about 1,000 volts. At that time Dr. Hopkinson had just drawn attention to some possible danger that might result from electrostatic capacity on the part of the transformers used, and it immediately occurred to the speaker, as it did to others at the same time, that that difficulty might be remedied or diminished by connecting the secondary circuit to the earth, and in these transformers exhibited in 1885 the secondary circuit was connected to an earth-plate. On mentioning this Prof. Elihu Thomson, of America, wrote to one of the technical journals to say that he had suggested that method before, and thereupon Prof. Ayrton and Perry wrote also to the same journal to say that they had suggested it before Prof. Elihu Thomson, and there the matter rested. He might also mention as an interesting fact in connection with these transformers that Mr. Ziperowski had arranged a method of self regulation which was not very unlike that which had been sketched on the board by Prof. Ayrton. He could not for the moment trust his memory for the exact details of the method, but it would be found in one of Mr. Ziperowski's specifications for the year 1885. The principle of that method was the use of an additional transformer, which was so arranged that when the terminal volts at the main transformers were lowered this additional transformer raised them again, or tended to raise them again, to the normal value.

The meeting then adjourned.

Mr. Lamb commenced the adjourned discussion on February 23rd, and spoke of the experiments carried out by Prof. Ayrton to determine the efficiency of the Kapp and Snell transformer.

Mr. J. E. H. Gordon, while fully appreciating the scientific interest of these appliances and the great practical use that had been made of them, could not help feeling that it was a pity to see so much ingenuity, so much skill, and so much labour lavished on what, in his opinion—possibly he might be wrong—could only be intended for a makeshift to enable them to go on until something better was ready. If he might be pardoned for putting into a scientific discussion a word of autobiography he might say he was not altogether incompetent to speak on the development of alternate current machines, for he supposed few people had been so deeply committed to them as he had been, or had to do with the actual practice of such large ones, and yet, even at the expense of abandoning every patent that he held, he had been so far convinced of the superiority of the method of distribution by storage batteries that he preferred to abandon his own system. They had all heard with a thrill of interest and delight of the 42ft. machine. It was not quite a new thing to think of these machines, although it was a new thing to give an order for them. He had made sketches of one in fact, but gone as far as the working drawings about a year and a half ago, and he admitted he was much tempted to go on. It would be very delightful to have such a machine. It would be worth running a great deal of risk merely to see such a mass of machinery moving and going round above your head, but to quote a French expression, "*C'est magnifique, mais ce n'est pas la guerre*," which may perhaps be translated by saying that that delight would be more felt by the engineer than the shareholder. He was not speaking of the abandonment of alternate current machines, nor was he speaking of them as if they had been failures, or as if they did not work economically. His alternate current installation at Padlington had worked for two years, and was now working, and in one year they had supplied 800,000 units of electricity. It was supplied at a price that was extremely low, and which they should not shrink from. It was only from reasons which he would give in a moment, which he hoped would be convincing, that he thought storage batteries were better; not because alternate current machines were bad, but because he thought there was something else better, and therefore he had determined to abandon them. The first consideration was the space occupied by these machines. They knew that experiments had been made for employing a number of small alternate current machines, and that these experiments had been successful at the South Foreland, but that was because they were working with arc lamps. Many people had tried to work alternate machines in parallel, but they did not work together till they had jumped for three or four minutes. Now three or four minutes jumping in the big machines might take a month's life out of 20,000 lamps, and that loss was rather a serious difficulty. Therefore they might take it in practice—he was now talking of what might be done in the laboratory—that they would use a couple of alternating machines, and that they must have very large machines if they were to get alternate currents to do the work. Those machines took up a dreadful amount of space. He did not think 10ft. diameter was an out-of-the-way size for a machine to give 200 to 250 units per hour, and that was what their Padlington machines were doing. Mr. Crompton was now making him machines with armatures 16in. in diameter, and two of these will do the same work as one of the 10ft. machines. If they had alternate current machines they must practically be placed outside the town, and the wires and machinery must be brought into the town. But with these modern direct current machines, and with modern engines such as Mr. Williams was making for them, they could pack the machinery so close that they could get an immense power in a small place, and none of the neighbours were any the wiser. His Company, the Whitehead Electric Supply Company, were, at this moment, putting in power within a quarter of a mile of this place for 10,000 lights and for

room in the engine house to extend the supply to 20,000 lights. They were using an engine-house 86ft. by 40ft. That included boilers, batteries, and everything else. It might be said that 20,000 lights were a drop in the cup in London lighting, and they had to face the question as to whether they were going to put up very large stations or make numerous stations of about 20,000 lights. They all knew that one of the advantages of central station lighting was the great economy in management and working that was obtained by increasing the number of lights from one station. But that increase did not go on indefinitely. Now, if they had got about 500 lights, they would find, roughly speaking, that the cost for wages in the 500 light plant would be about 10s. per lamp per year. When they went up to 10,000 lights, they would reduce that to perhaps 1s. 2d. per lamp per year. But after 20,000 lamps they did not get any further decrease in the wages, because they must have more machinery—they must have more room and more men, and it increased *per capita*. Therefore there was no doubt an advantage in having more than one station to work more than 20,000 lamps. They had the further advantage that if there were a number of stations of from 10,000 to 20,000 lamps, and they were working with direct current, they could couple these stations together. One might be working at one end of a main, and one at another; and if anything went wrong at one station the other station could help it out. There were certain definite reasons which he thought would always make a number of small direct current machines more economical in working than any big machines, and he would go somewhat briefly into it. The first was a reason which he could explain better by a diagram, which he had had placed on the wall (Fig. 1), showing the curve of output of current for a residential district and taken from actual figures. That diagram showed that the maximum demand was very much greater than the average. Hotel districts and club districts showed different curves. The diagram represented hours from six one morning to six the next morning. The vertical ordinates showed the number of lamps, and assuming that the installation was wired for 20,000, the number of lamps was small till about three o'clock, say, on a winter afternoon. Then it rose pretty steadily and regularly till about six o'clock. Then it went up in a rush. Then it came down and remained pretty nearly constant from about half past eight till about ten. That was the time when the first batch of people went to bed. Then it sank gradually. There was apparently a great line of virtue about ten o'clock. People who stayed up after ten o'clock seemed to be reckless of hours of morality, and merely dropped off one by one until the morning. The reason of the rise between seven and half past was rather curious. That was the time when people went up stairs to dress for dinner. About the same time the servants are laying the cloth in the dining room. So it happened that that was the only time that the lights in the dining room and the bed rooms were lit at the same time. That sent the current up with a rush. Assuming that they were working with an alternate-current machine, with 20,000 lights wired, and they had, say, 15,000 lamps in use, in order that there should not be a break down they must have their machine powerful enough for 15,000, and that meant not only that the alternate-current machine, but that the engine, boilers, dynamos, and engine house must all be up to that size. Assume also that they were supplying by a contract based on meter. It would then be evident that a great portion of the machine was only earning money for an hour and a half in the 24 hours, and that half the power of the machine was wasted for at least 12 hours out of the 24. But the interest on the cost of the machine was going on for the whole 24. Now let them see what would happen if they had storage batteries. Assume first of all that they were going to have a moderate amount of storage and would work their machines for 12 hours. The quantity of electricity for the day was shown by the area of the demand curve, that showed the number of units—and the area of this second curve, or 12 hours' supply, must be the same as the area of the demand curve, showing the quantity required for the day. If they had storage and worked their engines for 12 hours, the maximum current need only be current for 4,550 lamps. The size of the engines, boilers, and boilers was fixed by that. Therefore, for 20,000 lamps, with an occasional supply of 15,000 at once, it was not necessary to have, by storage, machinery of greater capacity than 4,550. If, however, they decided to work their engines for 24 hours—which might in some circumstances be advisable—they could then have something much smaller still. He supposed in practice, what they would do in designing a new installation would be to so arrange that the engines, when they are first put down, are to work twelve hours to meet the demand, and then as custom comes in they could decide according to circumstances whether they would increase their engine power, or whether they would increase their battery power and work longer hours. But probably they would commence working twelve hours and increase the hours of working as custom came in. He must further point out that whatever percentage loss there might be in the storage batteries must be calculated not on the whole area of the curve but only on those portions of the supply and demand curve which do not overlap—a very different thing. That dealt with the capital cost of the plant. The next point was the efficiency of the dynamo. Mr. Mackenzie knew perhaps even better than he himself, and that the efficiency of the alternate-current dynamo was quite different when it was fully loaded from what it was when not loaded, and the alternate-current dynamo that would give, say, 4,000 horse-power a day, and give a very good efficiency, say 90 per cent., or whatever it might be, would not have anything like that efficiency when the dynamo was working at a half or a third or a quarter of its power. There was, however, a much more important point than that. The alternate-current machines, whether used direct, as was their practice in Washington, or when used in these transformers, required for their successful operation that the number of alternations per second should be sensibly constant—that is they must not greatly vary the speed of the engines and the speed of the dynamos. They must run their engines at very nearly the same speed, whether they were giving their full power, or

whether they were giving only a fraction of their power. He would ask them what the diagram of a quadruple expansion engine of 5,000 horse power would be, working at full speed at 1,500 horse-power. Probably two cylinders would be working one way, and pulling the other two round, and the diagram would be of a somewhat peculiar nature. Experience showed that a compound engine, working at full speed at a third of its power, burnt at least twice as much coal per horse-power as when it was working at its full power. Now, these smaller engines that were used for storage current might be easily coupled together. They worked their engines at their full power until they had obtained the storage they wanted, and then they stopped. The engines were either worked at their full power or were stopped. Therefore they were bound to get a far better economy than could be obtained by working big compound engines at half their power. There was another reason for scattering stations and placing them where you could use engines that would not be a nuisance in great populous districts. London was now being filled with great buildings, residential flats, great hotels, and buildings of that sort, and the best site of a station was somewhere near one of these, where they could use their lamps to begin with as there they could for the first time meet the gas companies on their own

WIRED FOR 20,000 LAMPS

FIG. 1.

ground, and utilize waste products. At Whitehall he had taken a contract to sell a quantity of hot water day by day that would use up the whole of his waste steam, and thus what was formerly an expensive nuisance was converted into an important source of revenue. He did not, however, wish to be too precipitate in his condemnation of the transformer. These were two systems both endeavouring to do their work as best they knew. He felt that his friend Mr. Mackenzie was doing good work in educating the public to the use of electric light, and persuading them to wire their houses. Mr. Mackenzie's customers would, he hoped, then transfer their custom to him on seeing the advantages of the storage system. Perhaps they must not allude to it too particularly, but they might remember that there was yet a third system of electrical distribution which they had heard of a great deal within the last few weeks, which he thought none of them would wish to assist more than they could, and that was the system of distributing electricity from house to house by means of circuiters.

Mr. Crompton said they were discussing two papers on transformers, and he thought his friend Mr. Gordon had rather wandered away from the subject. He hoped they would check him if he wandered away in the same direction, because there was a great tendency to do so. The subject of transformers, taken by itself, viewed more particularly from the side Mr. Kapp had viewed it, was of a somewhat dry nature, and they would, he hoped, excuse him if he tried to infuse a little more liveliness into the discussion. The lighting of the future, so far as they knew at this present moment, was going to be handed over to the one system or the other, to battery transformers or to alternate-current transformers. He considered that the question that these papers had raised at the present moment were of supreme importance. The company that he had been more particularly speaking of for which they had the highest respect—the Grosvenor Gallery people, had done a very great work, and he thanked them most heartily for educating the people of London to like the electric light. They were showing how people would put up with any sort of light. It was very difficult to follow a very good man over his ground, but it was very much easier to beat a man who was not quite so good, and in that case he thought the Grosvenor Gallery gentlemen would excuse him if he said that they had a little to learn still in the way of producing the electric light. Hitherto they had produced illuminations which were not altogether pleasant to people who were sitting at five o'clock tea in a Mayfair drawing room. He believed that Mr. Mackenzie had explained many of the causes of these things, which of course they must not laugh at; but as an opponent he took advantage of them, because he believed they were inherent in the system. He believed that with the alternating transformer system, as at present arranged, they were greatly dependent on what their neighbour did, and that accidents to their neighbour's transformer affected an innocent person several blocks off in a way that could not happen with the direct system by distribution carried on from a series of accumulating or storage centres. He had long had the two systems before him, and he had been working

at the subject for the last two or three years. As most of them knew he had carried out central stations in which the transformation from high-tension currents of 500 volts had been carried down to 100 volts, usually employed in incandescent lamps by means of four batteries in series. He had data from these installations, and data which were of use. It was no use in such a place as that to discuss the question of management—that is to say, wages and matters of that kind—but it was of great use to discuss the scientific engineering part of it, that is, the question of which system worked with the least horse power, which worked with the least first cost in machinery, the least first cost in mains, and the greatest steadiness and regularity and freedom from breaks down. From these points of view he proposed to compare the system of alternating transformers with the system of battery transformers.
